Abstract

The extent to which discrimination can explain racial wage gaps is one of the most divisive issues in the social sciences. Using a newly available data set, this paper develops a simple empirical test which, under plausible (but not innocuous) conditions, provides a lower bound on the extent of discrimination in the labor market. Taken at face value, our estimates imply that differential treatment accounts for at least one third of the black-white wage gap. We argue that the patterns in our data are most naturally rationalized through a search-matching model in which employers statistically discriminate on the basis of race when hiring unemployed workers, but learn about their marginal product over time.

*We give special thanks to Alan Krueger for access to the New Jersey data used in this paper. We also thank Joseph Altonji, David Card, Kerwin Charles, William Hubbard, Lawrence Katz, Kevin Lang, Steven Levitt, Julie Mortimer, Derek Neal, Ariel Pakes, and Betsey Stevenson as well as seminar participants at the University of Chicago, NBER, and RWI Essen for helpful comments and discussions. We are also grateful to Joseph Altonji and Charles Pierret for sharing their data and programs with us. Vilsa Curto, Peter Evangelakis, Iolanda Palmieri, and Wonhee Park provided excellent research assistance. A portion of this paper was written while Fryer and Spenkuch visited the Erwin Schrödinger Institute in Vienna, Austria. Financial support from the German National Academic Foundation [Spenkuch] is gratefully acknowledged. Correspondence can be addressed to the authors at Department of Economics, Harvard University, 1805 Cambridge Street, Cambridge MA 02138 [Fryer]; Department of Sociology, Princeton University, 157 Wallace Hall, Princeton NJ 08544 [Pager]; Kellogg School of Management, Northwestern University, 2001 Sheridan Road, Evanston IL 60208 [Spenkuch]; or by e-mail: rfryer@fas.harvard.edu [Fryer], pager@opr.princeton.edu [Pager], or j-spenkuch@kellogg.northwestern.edu [Spenkuch]. The usual caveat applies.

1 Introduction

In the past five decades, social scientists have attempted to identify discrimination in a variety of ways. These include estimating residual wage gaps net of the effect of observable characteristics and pre-market skills (Corcoran and Duncan 1979, Reimers 1983, O’Neill 1990, Neal and Johnson 1996, Black et al. 2010, among others), developing structural models of the labor market (e.g., Bowlus and Eckstein 2002, Eckstein and Wolpin 1999), as well as audit studies and related experiments (e.g., Ayres and Siegelman 1995, Neumark et al. 1996, Bertrand and Mullainathan 2004, Pager 2007).

Surprisingly, these approaches arrive at starkly different conclusions. While experimental and structural analyses often report differential treatment by race, the best available reduced form evidence seems to suggest that “the black-white wage gap primarily reflects a skill gap” (Neal and Johnson 1996, p. 869) and that “labor market discrimination is no longer a first-order quantitative problem in America” (Heckman 1998, p. 101).

However, all of these methods are subject to important limitations. Estimating Mincerian equations to account for racial differences in individuals’ endowments and pre-market factors will misstate the extent of discrimination if skill bundles or other important characteristics are unobservable. Structurally modelling unobserved heterogeneity side-steps this issue, but comes at the cost of imposing parametric restrictions; and (quasi-)experimental evidence of differential treatment by race may mistake discriminatory tastes of the average employer for market discrimination (Heckman 1998).¹

Gaining a better understanding of the impact of labor market discrimination on racial wage gaps is of great importance, as the appropriate policy lever, if any, depends critically on the answer. If discrimination is quantitatively important, then the case for anti-discrimination policy or even “affirmative action” may be justified. If, however, racial wage gaps are determined before individuals enter the labor market or if discrimination is not a first order problem, then the case for government intervention is much weaker.

Using rich longitudinal data on a large sample of unemployed workers in the state of New Jersey who completed weekly interviews for up to twelve weeks, we develop a simple test for the presence of racial discrimination in the labor market. Four features of this data set – information

¹In addition to these points, Charles and Guryan’s (2011) discussion of challenges to identifying discrimination also emphasizes that individuals’ self-identified race is a social construct, which may be endogenous to labor market success; thereby complicating the identification of discrimination.

on search behaviors and search strategies, data on offered (as opposed to only accepted) wages, administrative information on previous earnings, and timing (data were collected during a period of mass unemployment) – enable us to conduct a novel test of racial discrimination in job finding and offered wages. The key idea is that under the null hypothesis of “equal treatment,” wages will closely resemble a worker’s marginal product. Hence, conditional on wage on the previous job, there should be no racial differences in wage offers. By controlling for previous wage, we account for the *market valuation* of skill bundles, non-cognitive skills, and similar variables that previous research treated as unobservable. Finding racial differences after controlling for previous earnings would thus lead us to reject the null of no discrimination.

This approach rests on two important identifying assumptions. First, we assume that, *ceteris paribus*, blacks and whites draw job offers from a comparable set of firms in similar markets, which implies that search intensities, search strategies, discount rates, and so on do not differ significantly across racial groups. This assumption is partially testable. Adding controls for hours spent looking for a job, how many firms an individual contacted, the types of jobs to which she applied, bargaining behavior, or discounting does not significantly alter the results.

The second assumption is that previous wage does not systematically overstate blacks’ productivity relative to that of whites. If previous wage equals marginal product, then this assumption holds and our approach will correctly identify racial discrimination. If previous wage is a function of both productivity and differential treatment by race, then our approach will provide a *lower* bound on the impact of discrimination. Conversely, if previous wage captures marginal product plus a diversity preference or the effect of affirmative action, then assumption two is violated and we will overstate the amount of discrimination in the market. Unfortunately, this assumption is not directly testable.

The bottom line is simple: if one believes that, conditional on previous wage, blacks are at least as qualified as whites, then our approach identifies a lower bound of discrimination in the labor market. If one believes the opposite to be true, then our approach is invalid.²

The results from our test of racial discrimination in the labor market are both interesting and informative. While the raw black-white gap in our data – -0.404 log points – is slightly larger than the gaps in commonly used data sets such as the CPS, Census, or NLSY79; controlling for previous

²Our findings are qualitatively robust to potential confounding factors such as mean reversion in wages, severe measurement error, or different empirical models. Robustness checks on these dimensions are contained in Appendix C. If the effects of discrimination accumulate with labor market experience, then our lower bound is not likely to bind. We thank Betsey Stevenson for making this point.

wage decreases the gap to -0.169 (.056). Adding additional controls for industry, occupation, duration of unemployment, bargaining behavior, geographic characteristics, search behavior and search intensity, discount rates, and metropolitan area fixed effects reduces the gap by at most 0.042 log points. Thus, under assumptions one and two above, our data reveal that the impact of racial discrimination on offered wages is at least one third of the raw gap for blacks.³

Though these results do not depend on the the particulars of any economic theory, we argue that our empirical findings are most naturally rationalized by a search-matching model of the labor market – similar to the that developed in Jovanovic (1979) – in which employers statistically discriminate based on race when hiring from the market, but learn about their employees productivity over time. The model has three stages. In the first stage, unemployed workers are stochastically matched with firms. After observing a productivity signal the firm offers a worker her expected marginal product, and the worker decides whether or not to accept the offer. If she declines, she remains unemployed, but has the chance of being rematched in the next period. If the worker accepts, she works for one period, and in the next period both the worker and the firm learn the true productivity of their match. Firms then offer a worker her match-specific marginal product. The worker decides whether to continue the employment relationship (until an exogenous separation occurs), or to enter unemployment and search for a better match.

The model’s predictions are borne out in the data. As in Black (1995), the presence of statistical discrimination in our search-matching model implies that reservation wages are lower for blacks. Empirically, we estimate that blacks have a 7% lower reservation wage than similar whites. Moreover, if blacks are more likely to incur a job separation than whites, then the model predicts that the aggregate black-white wage gap may increase with age or experience *across* firms. This fact has been documented by Altonji and Blank (1999), Altonji and Pierret (2001), and Oettinger (1996). Within firms, however, racial wage gaps are predicted to *decrease* with tenure, as employers learn about a worker’s marginal product. Using both our data and detailed data on work histories from the National Longitudinal Survey of Youth 1979 (NLSY79), we show that the data support this prediction. In our data from the state of New Jersey, for instance, blacks experience a 1.1 percentage points higher return to tenure than whites. Extending the empirical work of Altonji and Pierret (2001), we demonstrate that although the black-white wage gap widens by 0.9 percentage points per year of potential labor market experience, it decreases by 1.2 percentage points per year

³These estimates are similar to those recently reported in Lang and Manove (2011) using the NSLY79 and controlling for educational attainment as well as a test score taken when individuals were in middle or high school.

of tenure with a given employer.

Finally, our analysis addresses a common critique of statistical discrimination models (e.g., Neal 2006). Simple models of this kind predict lower returns to education for blacks than for whites. Yet, if anything the opposite appears to be true empirically. While we do not model human capital investments directly, our dynamic search-matching model of statistical discrimination is flexible enough to account for this important point. For instance, blacks may experience weakly higher returns on investment in our model if education reduces the variance in the signal to employers (for empirical evidence see Arcidiacono et al. 2010), or if educational attainment decreases the probability of job loss (Kletzer 1998); thereby letting blacks garner larger returns to tenure.

Although our model of statistical discrimination is consistent with the patterns in our data and sidesteps common critiques of such models, we cannot rule out other forms of discrimination. Pre-market factors *alone*, however, cannot explain the full set of facts.⁴ Thus, taking our estimates at face value, labor market discrimination appears to be an important impediment to racial income equality. This suggests that alleviating racial inequality may take a combination of policies to both eliminate barriers to investing in pre-market skills and anti-discrimination enforcement so that minorities are appropriately rewarded for those skills.

The remainder of the paper proceeds as follows. The next section provides a brief overview of the literature on racial discrimination in the labor market. Section 3 outlines a search-matching model in which firms statistically discriminate on the basis of race. Section 4 describes the data used in our analysis as well as our econometric approach. Empirical evidence on racial differences in wage offers and job finding is presented in Section 5. Section 6 tests additional predictions of our model, and Section 7 discusses to which extent alternative theories may reconcile our findings. There are three appendices. Appendix A contains technical proofs, Appendix B describes the construction of our samples as well as the coding of variables, and Appendix C contains additional empirical results.

2 Race and the Labor Market

There exists a very large literature on racial differences in wages.⁵ In what follows, we divide the literature into three categories based on the strategy used to identify discrimination. The

⁴Charles and Guryan (2008) argue that taste-based discrimination in the spirit of Becker (1957) explains about one quarter of the black-white gap. While we cannot rule out that taste-based discrimination per se, the patterns in our data are inconsistent with models that rely exclusively on racial animus.

⁵For an excellent (though somewhat dated) review see Altonji and Blank (1999).

first section describes analyses using Mincerian equations and the assumptions needed to obtain causal estimates. The second section discusses the literature which imposes parametric restrictions to estimate structural models of the labor market; and the last section reviews experimental approaches. Broadly summarizing, the existing evidence is inconclusive as to whether discrimination is of first-order importance in today’s labor market.

2.1 Mincerian Equations

A large number of empirical studies estimate Mincerian equations and define labor market discrimination as the wage differential between racial groups net of a set of observable characteristics such as age, education, occupation, geographical location, and labor market experience (e.g., Corcoran and Duncan 1979, Reimers 1983, Smith and Welch 1986, Blau and Beller 1992, Oaxaca 1973, Oaxaca and Ransom 1994, Darity and Mason 1998). While this approach is useful in accounting for racial differences in endowments, it will identify the causal effect of discrimination if and only if *unobservable* determinants of individuals’ wages do not systematically differ by race. Therefore, estimates of racial discrimination in this tradition depend crucially on the set of included controls.

Corcoran and Duncan (1979) constitutes an early attempt to account for a comprehensive set of covariates. Their findings indicate that blacks and whites enjoy similar returns to observable characteristics; yet racial differences in these factors account for only half of the raw wage gap. The authors interpret this as evidence of pervasive discrimination. Similarly, paying careful attention to selection bias, Reimers (1983) estimates that discrimination is responsible for a up to 86% of the total difference in the wages between Hispanic and non-Hispanic white men, and for about 60% of the black-white wage gap.

Fairlie and Kletzer (1998) examine black-white disparities in job displacement and re-employment rates. They document approximately 30 percent higher rates of displacement and substantially lower re-employment probabilities for black workers. Although observable factors (in particular education and occupation) play an important role in accounting for the raw racial difference, a large fraction of the gap remains unexplained—leaving ample room for discrimination.

In stark contrast, the seminal contributions by O’Neill (1990) and Neal and Johnson (1996) demonstrate that racial disparities in wages narrow dramatically – and sometimes even reverse – upon accounting for a measure of pre-market skill. More specifically, using data from the National Longitudinal Survey of Youth 1979 (NLSY79), Neal and Johnson (1996) report that conditioning only on age as well as an individual’s score on the Armed Forces Qualification Test (AFQT) reduces

the raw racial gap in wages by more than 70%. The resulting residual black-white wage differences are $-.072$ and $.035$ log points for men and women, respectively. Based on this evidence Neal and Johnson (1996) – as well as many subsequent observers – conclude that the black-white wage gap is primarily due to differences in pre-market skills as opposed to discrimination. And, thus, it is often argued that appropriate public policies for alleviating racial differences in wages should be aimed at eliminating the hurdles black children face in acquiring marketable skills (e.g., Fryer 2011).

Lang and Manove (2011), however, point out that racial gaps in wages re-emerge when one controls for educational attainment in addition to AFQT scores (see also Carneiro et al. 2005). More specifically, they show that the gap increases from $-.09$ to $-.15$ log points when including years of schooling in Neal and Johnson’s (1996) original specification, and argue that when one controls for AFQT performance, blacks have higher educational attainment than whites and that the labor market discriminates against blacks by not financially rewarding them for greater education.⁶

2.2 Structural Models of the Labor Market

Recognizing the inherent problems of the Mincerian approach, another strand of the literature develops structural models of the labor market in order to estimate the effect of discrimination (e.g., Wolpin 1992, Eckstein and Wolpin 1999, and Bowlus and Eckstein 2002, among others). Blinder (1973), for instance, uses a simultaneous equation specification to account for the endogeneity of education and union status. He estimates that between 40% and 70% of the racial gap in the Panel Study of Income Dynamics (PSID) is due to discrimination.

However, if individuals engage in costly job search, then the distribution of observed wages will not correspond to the distribution of wage offers, and estimates of discrimination based on the former may confound disparate treatment with any other factor determining reservation wages, in particular search costs. To address this issue, Eckstein and Wolpin (1999) develop a two-sided search-matching model which delivers an *upper* bound on the impact of discrimination. Estimates from the NLSY79 indicate that discrimination can potentially explain the entire gap.

Similarly, in an attempt to disentangle unobserved productivity differences from discrimination by firms, Bowlus and Eckstein (2002) estimate an equilibrium search model in which some employers incur disutility from hiring blacks. Their results imply that the productivity of blacks is on average

⁶In an appendix Neal and Johnson (1996) show that conditional on both AFQT and education racial wage gaps are larger at the bottom of the education distribution and smaller at the top. Lang and Manove (2011) argue that the convergence at high levels of skill is a consequence of statistical discrimination, since informational asymmetries likely decrease for college graduates.

only 3.3% lower than that of whites, whereas employers' distaste for blacks is equivalent to 31% of whites' productivity level, and 56% of firms discriminate. An important limitation to the structural approach is its reliance on restrictive assumptions to ensure identification.

2.3 Field and Quasi-Experiments

A third branch of the literature seeks to identify discrimination by using field and quasi-experiments. In-person audit studies, for instance, compare the probability of receiving a callback or job offer across carefully matched pairs of black and white individuals who pose as applicants in real world job searches (e.g., Turner et al. 1991, Bendick and Reinoso 1994, Pager 2003, Pager et al. 2009).⁷ Almost uniformly these studies find that black testers fare substantially worse than their white counterparts; which is commonly interpreted as strong evidence of discrimination. However, as emphasized by Heckman (1998), the validity of this approach depends crucially on the assumption that tester pairs are not only similar on observables, but that the distribution of unobservable characteristics does not differ by race. Moreover, it is not possible to infer market discrimination from discriminatory tastes of the average employer (cf. Becker 1957).

Correspondence studies provide a partial solution to the first concern (see, for instance, Firth 1981, Esmail and Everington 1993, or Bertrand and Mullainathan 2004). Bertrand and Mullainathan (2004) send almost 5,000 fictitious resumes with randomly assigned black- or white-sounding names to over 1,200 help-wanted ads in Boston and Chicago. *Ceteris paribus*, white-sounding names receive about 50% more callbacks. Yet, it remains unclear whether the marginal (as opposed to the average) employer treats blacks and whites differently.

The approach we take in this paper combines aspects of the Mincerian and structural literatures. Our empirical work is strongly guided by theory, but uncertainty over which form of discrimination is generating the data leads us to eschew structurally estimating the parameters of our model. Instead, the richness of our data permits reduced form estimation of parameters which are typically structurally estimated such as arrival rates, reservation wages, or wage offer distributions.

Ultimately, our contribution to the literature on labor market discrimination is three-fold: (i) We provide the first descriptive details of racial differences in search behavior from a large sample of job seekers; (ii) we develop a novel empirical test which, under plausible conditions, provides a lower bound on the extent of discrimination; and (iii) we show that the patterns in our data

⁷There also exists a large (quasi-)experimental literatures on discrimination in housing and product markets. See Riach and Rich (2002) for a useful review.

are consistent with a search-matching model of the labor market in which employers statistically discriminate based on race.⁸

3 A Search-Matching Model of the Labor Market

To fix ideas and to provide a framework for interpreting our empirical work, this section outlines a simple search-matching model of the labor market. Although our interpretation of the data is heavily guided by theory, it is important to emphasize that our empirical test for discrimination is general and does not depend on the specifics of the model.

The model is a discrete time simplification of Jovanovic (1979), along the lines of that developed in Sargent (1987) and Prescott and Townsend (1980), with statistical discrimination. First, we describe the case in which there are no racial differences and firms do not discriminate on the basis of race. We then briefly describe how one introduces these features.

Let there be a unit mass of infinitely lived individuals who are looking for work. Each period unemployed workers and firms are randomly matched with probability $\delta \in (0, 1)$. An agent's marginal product is match-specific and denoted by θ .

Workers maximize the present discounted value of wages. But before a matched worker receives an offer, she and the firm observe a common noisy signal of her productivity, $\theta + \xi$. We assume that θ and ξ are independently and normally distributed random variables: $\theta \sim N(\mu, \sigma_\theta^2)$, $\xi \sim N(0, \sigma_\xi^2)$. Using Bayes rule, both the worker and the firm draw inferences about θ . That is, conditional on having observed $\theta + \xi$, θ is distributed normally with mean $\omega = \frac{\sigma_\xi^2}{\sigma_\theta^2 + \sigma_\xi^2} \mu + \frac{\sigma_\theta^2}{\sigma_\theta^2 + \sigma_\xi^2} (\theta + \xi)$ and variance $\sigma_{\theta|\theta+\xi}^2 = \frac{\sigma_\theta^2}{\sigma_\theta^2 + \sigma_\xi^2}$.⁹

To simplify the analysis we assume that firms operate in a perfectly competitive market with free entry. Moreover, firms employ a constant returns to scale technology for which labor is the only input. In equilibrium, each firm offers an initial wage $\omega = E[\theta|\theta + \xi]$, with the understanding that in subsequent periods it will pay the worker its marginal product as it obtains more information about θ .¹⁰

Given this strategy of the firm, the worker must decide whether to accept the offer and work this period receiving ω , or to refuse and remain unemployed for one period with a chance of being

⁸Our evidence is consistent with the findings of List (2004) for the sportscard market. List (2004) conducts a series of complementary field experiments demonstrating that statistical as opposed to animus based discrimination is the reason why minorities receive lower initial and final offers in this market.

⁹One can show that the forthcoming results generalize if we dispense with the normality assumption and assume that the wage is stochastically increasing in the signal (cf. Border 1996).

¹⁰Jovanovic (1979) proves that this constitutes an equilibrium strategy—although there do exist other equilibria.

matched with another firm in the next one. If she accepts, her true productivity is revealed in the subsequent period. After learning her marginal product, the firm offers to pay θ until the match is exogenously terminated (which occurs with probability $\alpha \in (0, 1)$ at the end of every period). The worker then decides whether to accept or reject this offer.

Let $J(\theta)$ denote the expected present value of wages of a worker whose marginal product is known to be θ with certainty and who behaves optimally. If she accepts the offer, the value of the match is given by $\theta + \alpha\beta Q + (1 - \alpha)\beta J(\theta)$, where $\beta \in (0, 1)$ is an exogenously determined discount factor and Q denotes the expected present value of wages if unemployed. Workers who reject the match are unemployed this period with the chance of being rematched in the next one. Thus, we can write Bellman's functional equation as

$$J(\theta) = \max\{\theta + \alpha\beta Q + (1 - \alpha)\beta J(\theta), Q\}.$$

This equation is graphed in Figure 1. It admits a solution of the familiar form:

$$J(\theta) = \begin{cases} \frac{\theta + \alpha\beta Q}{1 - \beta(1 - \alpha)} & \text{for } \theta \geq \theta^* \\ Q & \text{for } \theta < \theta^* \end{cases} \quad (1)$$

As is typical in these models, workers follow a reservation wage policy: accept offers $\theta \geq \theta^*$ and reject offers $\theta < \theta^*$, where θ^* solves

$$\theta^* = (1 - \beta)Q. \quad (2)$$

We now turn to the worker's choice in the intermediate stage. After being matched with a firm and having observed $\theta + \xi$, the worker has to decide whether to accept a wage offer ω and thereby retain the option value of learning θ .

Let $V(\omega)$ be the expected present value of wages of a worker who has an initial offer ω in hand and who behaves optimally. Then,

$$V(\omega) = \max\{\omega + \beta \int J(s) dF(s|\omega, \sigma_{\theta|\theta+\xi}^2), Q\},$$

where $F(s|\omega, \sigma_{\theta+\xi}^2)$ denotes the posterior cumulative distribution function of θ , conditional on $\theta + \xi$. Note that both ω and $\beta \int J(s) dF(s|\omega, \sigma_{\theta+\xi}^2)$ are increasing in ω , whereas Q is constant. Thus, workers again follow a reservation wage policy. The functional equation has the solution

$$V(\omega) = \begin{cases} \omega + \beta \int J(s) dF(s|\omega, \sigma_{\theta|\theta+\xi}^2) & \text{for } \omega \geq \omega^* \\ Q & \text{for } \omega < \omega^* \end{cases}, \quad (3)$$

and the reservation wage, ω^* , in the intermediate stage is implicitly defined by

$$\omega^* + \beta \int J(s) dF(s|\omega^*, \sigma_{\theta+\xi}^2) = Q. \quad (4)$$

In equilibrium, the average accepted wage of workers in the intermediate stage is given by

$$E[\omega|\omega \geq \omega^*] = \frac{\int_{\omega^*}^{\infty} \omega dG(\omega|\mu, \sigma_{\omega}^2)}{1 - G(\omega^*|\mu, \sigma_{\omega}^2)},$$

and that of tenured workers equals

$$E[\theta|\theta > \theta^*, \omega > \omega^*] = \frac{\int_{\omega^*}^{\infty} \int_{\theta^*}^{\infty} s dF(s|\omega, \sigma_{\theta|\theta+\xi}^2) dG(\omega|\mu, \sigma_{\omega}^2)}{\int_{\omega^*}^{\infty} \int_{\theta^*}^{\infty} dF(s|\omega, \sigma_{\theta|\theta+\xi}^2) dG(\omega|\mu, \sigma_{\omega}^2)}.$$

It is straightforward to verify that mean wages decrease when workers are willing to accept worse matches, i.e. as reservation wages decline. In Appendix A, we also prove that $\theta^* > \omega^*$. Consequently, wages rise on average with tenure in the firm, but decrease as tenured workers lose their jobs and are being rematched.

To close the model, the present discounted value of wages when unemployed is given by

$$Q = \delta\beta \int V(\omega) dG(\omega|\mu, \sigma_{\omega}^2) + (1 - \delta)\beta Q, \quad (5)$$

where $G(\omega|\mu, \sigma_{\omega}^2)$ denotes a normal cumulative distribution function with mean μ and variance $\sigma_{\omega}^2 \equiv \frac{\sigma_{\theta}^4}{\sigma_{\xi}^2 + \sigma_{\theta}^2}$.

The model generalizes straightforwardly to incorporate a variety of differences in worker characteristics. After all, each parameter in the set $\{\beta, \alpha, \delta, \mu, \sigma_{\theta}^2, \sigma_{\xi}^2\}$ can vary by group identity. If groups differ on observable characteristics, such as race, and if these characteristics are correlated with any of the parameters, then firms will treat each group of workers as if they belonged to a separate market of that type. In particular, under the assumptions above it continues to be an equilibrium to pay each worker her expected marginal product, given all available information (cf. Jovanovic 1979). There are thus many ways to introduce racial disparities in wages.¹¹

¹¹Of course, there exist many other equilibria. For instance, search frictions and the existence of market power may induce firms to offer lower wages to groups of workers with lower reservation wages (Black 1995). Without free

Disparities in the arrival rate of matches due, for example, to differences in search behavior or discriminatory practices of firms can be captured by assuming that $\delta^B < \delta^W$. This relationship is reported in several audit studies in sociology and economics (e.g., Bendick et al. 1994, Pager 2003, Bertrand and Mullainathan 2004). From equations (2) and (5) it is straightforward to show that $\frac{d\theta^*}{d\delta} > 0$. Thus, if blacks are less likely to receive job offers, then they also have lower reservation wages and will accept worse matches. In equilibrium this results in racial wage gaps.

Blacks may also be more likely to lose their job (see Fairlie and Kletzer 1998). As reported in Stratton (1993), disparities in arrival and separation rates lead to large racial differences in unemployment rates. Moreover, it is easy to show that increasing the chance of an exogenous separation lowers the reservation wage, i.e. $\frac{d\theta^*}{d\alpha} < 0$. All else equal, this would result in lower wages for blacks.

Now, consider racial differences in the distribution of the match quality signal (Phelps 1972, Arrow 1973, Cornell and Welch, 1996, Lang 1986). In an Arrow (1973) model, the average of ξ differs between blacks and whites, resulting in racial differences in initial wage offers. Conversely, in a Phelps (1972) or Aigner and Cain (1977) framework, the variance of ξ is larger for blacks than for whites. In this case, employers put more weight on average group ability when evaluating blacks' signals than when inferring the ability of a white candidate. While this will not lead to mean differences in ω if both groups are equally skilled, if $\mu^B < \mu^W$ then black workers will, on average, receive lower wage offers than whites with the same signal. In either case, our model predicts the black-white wage gap to converge with tenure in the firm, since workers of equal ability earn the same wage after their true ability has been revealed. This prediction distinguishes our search-learning theory from traditional models of discrimination; and, as shown in subsequent sections, it is, indeed, borne out in the data.

4 Data and Econometric Approach

4.1 Data and Descriptive Statistics

The primary data set used in this paper was collected by the Princeton University Survey Research Center (PSRC) during the fall of 2009 and early 2010.¹² It is important to recognize that the

entry and a perfectly elastic supply of entrepreneurs biased employers may trade off profits for a desire to discriminate and survive in equilibrium. In order to fix ideas and to focus on the core aspects of job search as well as learning, we choose to maintain the simpler, more tractable—but admittedly less realistic—assumptions of Jovanovic (1979).

¹²In what follows we draw heavily on Krueger and Mueller (2011). For a comprehensive description of the sampling and interviewing procedures the interested reader should consult their appendix.

data were collected during a period of mass unemployment thereby lessening potential selection problems into the pool of UI recipients (Gibbons and Katz 1991). Although we have do not have compelling empirical evidence in favor of this assertion, it seems likely that layoffs during the 2009 recession were more random than during periods of a tight labor market.¹³

Starting from the universe of unemployment insurance (UI) recipients in the state of New Jersey as of September 28, 2009, PSRC drew a stratified random sample of 63,813 currently unemployed individuals. The sampled population was then contacted by the New Jersey Department of Labor and Workforce Development (LWD) and invited to participate in a confidential web survey for a period of 12 consecutive weeks.¹⁴

The survey consisted of an initial entry questionnaire and weekly follow-up interviews which were remarkably rich. The former elicited information on demographics, previous employment, asset holdings, and spouses' employment status; whereas the latter inquired about job search activities, time use, reservation wages, and job offers, among other topics. Participants were given the choice of receiving an incentive payment of \$20 within a few days of completing the entry questionnaire, or \$40 at the end of the 12 week survey period.

An important caveat to the data is that only 6,025 (roughly 10%) of the sampled individuals participated in the entry wave, and those who responded to the initial survey completed only about 40 percent of weekly follow-ups. The likelihood of responding varies by race. The sample of respondents consisted of 15.3% blacks (compared to 18.6% in the sample frame) and 68% of whites (relative to 61.7% in the sample frame).¹⁵ Participants were more educated, more likely to be female, and had higher previous earnings than the baseline population. Using rich administrative data, Krueger and Mueller (2011) create sampling weights in order to adjust for the stratified survey design as well as nonresponse. Comparing characteristics of respondents to the universe of UI recipients along a number of dimensions – including those that were not used to construct the weights (e.g. income, weekly exit rates from UI) – they conclude that the low response rate did not significantly skew the sample. After applying weights, blacks make up 20% of the sample

¹³In a seminal paper Gibbons and Katz (1991) argue that unemployed workers are negatively selected, and demonstrate that wage losses following displacement are larger after layoffs than plant closings (which presumably provide little or no signal about worker ability). Recently, Hu and Taber (2011) have shown that this holds only among white males, whereas blacks appear to suffer greater declines in wages following plant closings. Hu and Taber (2011) rationalize this finding by appealing to heterogeneous human capital. In Section 7 we argue that discrimination can rationalize this finding, as it may give blacks more of an incentive to invest in firm specific human capital than whites.

¹⁴Individuals who were unemployed for 60 weeks or longer at the beginning of the survey were later asked to participate in an additional 12 weeks of interviewing—for a maximum of 24 weeks. In this paper, however, we restrict attention to the first 12 weeks for all respondents.

¹⁵See Table 2.1 in Krueger and Mueller (2011).

(compared to 20.8% in the universe of UI recipients) and whites make up 59.8% (compared to 58.9%).

Throughout our analysis we use the weights created by Krueger and Mueller (2011), and follow their coding of wages by dropping wage offers below \$5 an hour and offers above \$100 per hour. Moreover, we restrict attention to respondents with non-missing information on race who are not listed as previously self-employed—for a final sample of 5,251 individuals. Appendix B provides additional detail on the construction of our sample as well as precise definitions of all variables.

Summary statistics for the variables used in our main specifications are displayed, by race, in Table 1, with “white” referring solely to non-Hispanic whites. Our primary outcomes of interest are offered wages and whether or not a job offer was received. Each of the follow-up surveys asked whether respondents had received any job offer within the last 7 days, if so how many, and what the wage associated with the best offer was.

In any given week about 6.5% of job seekers receive at least one job offer, and conditional upon receiving any offer approximately 84% of individuals are offered exactly one job. Blacks write 1.3 more applications per week than whites, but are slightly less likely to apply for white collar jobs.¹⁶ Interestingly, and in contrast to results in the audit study literature, blacks have 2.2 percentage points *higher* arrival rates than whites – at least in the raw data. However, the mean offered hourly wage for whites equals \$23.4, far in excess of the \$12.3 offered to blacks. And differences in the distribution of wage offers, as shown in Figure 2, are stark. The modal job offer is roughly the same across racial groups, but the right tail of the white offer distribution is significantly larger. A Kolmogorov-Smirnov test for equality in distributions is rejected at the 1%-level.

The remainder of Table 1 presents summary statistics for other variables used in our analysis. About 45% of white, and 58% of black respondents are female. On average blacks are almost 7 years younger than whites, and are much more likely to be single. Consistent with national patterns, blacks in our sample are less educated than whites. For instance, about 32% of white respondents report to have at least a college education, compared to 17% for blacks.¹⁷ Blacks have longer ongoing unemployment spells than whites, earned almost \$400 less per week on their previous job,

¹⁶Pager and Pedulla (2012) report that blacks and whites apply to similar jobs, but blacks consider a greater range of possibilities.

¹⁷Compared to unemployed New Jerseyites in the 2009 American Community Survey or the 2010 March CPS, respondents in our data report broadly similar educational attainment; although self-reported dropouts are somewhat under-represented and individuals with an incomplete college education are over-represented. It is important to note that the numbers pertaining to educational achievement in Table 1 do not match those in Table 2.1 of Krueger and Mueller (2011). In order to compare the sample of survey respondents to the universe of UI recipients they convert administrative data on years of schooling (for both populations) into “degrees”, but rely on self-reported educational attainment throughout the rest of their analysis.

and accumulated substantially less tenure than whites. We also have data on the industry in which an individual previously worked. Blacks are less likely than whites to have worked in construction and manufacturing. Instead, they are more concentrated in education and health care services.¹⁸

4.2 Identifying Discrimination

Four important features of the data described above enable us to conduct a novel test for racial discrimination: information on wage offers (as opposed to just accepted wages), search strategies and intensities, administrative data on previous earnings, as well as timing (the data were collected during a period of mass unemployment). Although the model outlined above guides our thinking about the data, the key idea of our empirical test is independent of the theory. Under the null hypothesis of no discrimination wages will proxy for marginal productivity. Hence, conditional on wage on the previous job, there should be no racial differences in wage offers, as controlling for previous wage implicitly accounts for the *market valuation* of all factors such as ability, non-cognitive skills, etc. which previous research treated as unobservable. Observing racial differences in wage offers after accounting for previous earnings would, therefore, lead us to reject the null of no discrimination.

More formally, let $\omega_{i,j}$ denote the wage associated with the j th job offer to individual i and consider the data generating process

$$\ln(\omega_{i,j}) = \kappa_0 + Race_i' \Gamma_0 + X_i' \beta_0 + \alpha_0 \theta_i + \nu_{i,j}, \quad (6)$$

where $Race_i$ is an indicator variable for i 's race, X_i are individual level covariates, θ_i denotes i 's unobserved ability, and $\nu_{i,j}$ is white noise.¹⁹ Although race and skill level will generally be correlated, if employers do not discriminate it must be the case that $\Gamma_0 = 0$.

Further assume that previous earnings, w_i , are related to unobserved skill in the following sense:

$$\theta_i = \mu + \lambda \ln(w_i) + X_i' \zeta + u_i,$$

where $\lambda \neq 0$, $E[u_i] = 0$, $\text{Cov}(X_i, u_i) = 0$, and $\text{Cov}(\ln(w_i), u_i) = 0$. This assumption is fairly benign, as a matter of statistically decomposing θ one can always write unobserved skill as a linear combination of previous earnings and individual level covariates. In this case, u_i corresponds to the least squares residual, which means that $E[u_i] = 0$, and $\text{Cov}(\ln(w_i), u_i) = 0$ are automatically

¹⁸Compared to the universe of UI recipients, construction workers are slightly under-represented in the weighted data (Krueger and Mueller 2011).

¹⁹We assume that skills command positive returns. That is, $\alpha_0 \geq 0$.

satisfied. For $\lambda \neq 0$ to hold it needs to be the case that even after controlling for X_i previous wages predict ability, as seems likely.²⁰

With this framework in mind, we can formalize our test of discrimination.

Proposition 1 *Let $\widehat{\Gamma}_{OLS}$ denote the ordinary least squares estimate of Γ in the empirical model*

$$\ln(\omega_{i,j}) = \kappa + \text{Race}_i' \Gamma + X_i' \beta + \phi \ln(w_i) + \varepsilon_{i,j},$$

and suppose that the true data generating process is given by (6). If (i) $\text{Cov}(\text{Race}_i, \nu_{i,j}) = 0$ and (ii) $\text{Cov}(\text{Race}_i, u_i) \geq 0$, then $\text{plim } \widehat{\Gamma}_{OLS} \geq \Gamma_0$.

Proof. See the Technical Appendix. ■

In words, the proposition implies that if assumptions (i) and (ii) hold one can reject the null hypothesis of no discrimination whenever $\widehat{\Gamma}_{OLS}$ is negative and statistically significant.

It is very important to note at the outset that the two identifying assumptions are not innocuous. Assumption (ii) requires that, conditional on covariates, previous earnings do *not* systematically overstate blacks' true ability. If, for instance, blacks were subject to discrimination on their last job, then they would earn less than equally skilled whites which implies that $\text{Cov}(\text{Race}_i, u_i) > 0$ and the assumption holds. Yet, if blacks actually earned higher wages relative to their white counterparts, say because previous earnings capture marginal productivity plus a diversity preference or whites have significantly more amenities that are not captured in previous wage, then $\text{Cov}(\text{Race}_i, u_i) < 0$ and our test will overstate the true amount of discrimination.²¹

Another potential violation of assumption (ii) arises from severe measurement error in previous wages. To see this consider the extreme case in which wages are pure noise. If blacks have lower mean ability than whites, then it will be the case that $\text{Cov}(\text{Race}_i, u_i) < 0$. More generally, assumption (ii) fails whenever previous wage is a noisy enough measure of productivity for blacks to appear to get paid more on average than their equally skilled white counterparts—despite the possible impact of discrimination. In an attempt to mitigate this concern, we use administrative data on previous earnings, which is likely much more accurate than the usual self-reported kind.

²⁰It is important to note that previous earnings, w_i , will generally *not* follow the same data generating process as wage offers, ω_i . For instance, workers might gain seniority, engage in additional training, or wages might rise with tenure in the firm as new information about workers' productivity arrives (cf. the model in Section 3). It would, therefore, be incorrect to set previous wages equal to wage offers and rearrange equation (6) to recover θ_i .

²¹Adding controls which proxy for whether an individual had health insurance on their previous job does not alter the forthcoming results.

In fact, administrative information usually serves as the *benchmark* in evaluation studies of various surveys (see, for instance, Rodgers et al. 1993, Bound et al. 1994, as well as the discussion in Bound et al. 2001). However, as individuals’ true productivity is unobservable we are ultimately not able to rule out this concern completely.²²

The first assumption is that $\text{Cov}(Race_i, \nu_{i,j}) = 0$; which is automatically satisfied if $\nu_{i,j}$ is in fact white noise. Intuitively, this assumption requires that, *ceteris paribus*, blacks and whites do not systematically differ in their search behavior and draw wage offers from a comparable sets of firms. If, for instance, blacks are more likely than whites to receive offers from firms particularly hard hit by the 2009 recession, then this assumption might be violated. Similarly, assumption (i) might fail if whites have lower discount rates and firms’ adjust their offers accordingly, or if blacks do not bargain as aggressively over offers as whites.

In contrast to the second assumption, however, assumption (i) is testable. Exploiting the richness of our data we can account for racial differences in search strategies, search intensity, geographic location, industry and occupation, bargaining behavior, as well as discounting. Reassuringly, there is little indication that differences along these lines explain our findings.

5 Racial Disparities in Job Finding and Offered Wages

5.1 Testing for Discrimination

Table 2 presents a series of estimates of racial disparities in offered wages. The coefficients therein correspond to the following empirical model:

$$\ln(\omega_{i,j}) = Race_i' \Gamma + X_i' \beta + \phi \ln(w_i) + \varepsilon_{i,j}. \quad (7)$$

All regressions include a full set of race indicators, with “white” serving as the omitted category. Consequently, the coefficients on race capture the gap between the named racial category and whites. Our primary emphasis, however, is on the black-white wage gap. The vector of other covariates included in the specification, denoted by X_i , varies across columns in Table 2. As one moves to the right, the set of covariates steadily grows. In all instances is the estimation carried out using weighted least squares with weights corresponding to the sampling weights calculated by

²²Another potential violation of assumption (ii) comes from differential selection into the pool of unemployed. If conditional on previous wage whites who are let go are more able than their black counterparts, then assumption (ii) would fail and the findings of our test would be invalid.

Krueger and Mueller (2011). Standard errors are clustered by individual to account for the fact that some job seekers receive more than one offer during the survey period.²³

The first column in Table 2 displays racial differences in offered wages after controlling for age and gender. The “raw” black-white difference is estimated to equal -0.404 log points, or approximately 33%. Accounting for racial disparities in formal education reduces the gap by .118 log points; but it remains economically large and statistically significant.

These estimates are somewhat larger than those obtained from commonly used data sets such as the CPS, or the NLSY79. Note, however, that there is an important difference compared to previous work. The estimates in Table 2 refer to wage offers as opposed to actual wages. The search model in Section 3 predicts that, depending on arrival rates and the shape of the wage offer distribution, racial differences in accepted wages may be smaller or larger than that in offers. For completeness, Table C.1 in the appendix displays estimates for accepted wages in the NJ UI data. Despite the fact that almost all papers estimating Mincerian regressions rely on self-reported wages, our preferred outcome is wage offers, as this allows us to circumvent potentially important selection bias in which offers workers accept.

Column (3) adds Log Previous Weekly Earnings to the set of controls.²⁴ As evidenced by the stark increase in R^2 , previous earnings are an excellent predictor of offered wages. Importantly, controlling for previous earnings almost halves the difference in offered wages between blacks and whites. However, with -0.169 log points the gap does remain economically large and statistically significant. On a purely descriptive level these results imply that blacks suffer a greater decline in wages after being laid off; and under the identifying assumptions of our approach, we can reject the null hypothesis of no discrimination.

Yet, so far it is unclear whether assumptions (i) and (ii) do, indeed, hold. In particular it is questionable whether blacks and whites receive job offers from a comparable set of firms, especially during the 2009 recession whose impact differed greatly by industry. To address this concern, the last two columns in Table 2 add controls for duration of unemployment, the reason why the last job ended, and previous industry fixed effects. While these factors are correlated with offered wages, the racial gaps remain almost unchanged. After controlling for previous earnings and the full set of

²³Due to the small sample size in the NJ UI data we pool males and females in our main regressions. For a detailed set of results differentiated by gender see Appendix C. Broadly summarizing, estimates of the black-white wage gap are qualitatively similar for males and females, but much more precise for the latter.

²⁴Since we have administrative data on average weekly earnings during the previous year, but only self-reported information on hours on the last job (which are reported to have “varied” in many cases), we choose to control for previous weekly earnings instead of hourly wages. Our main results are qualitatively and quantitatively robust to controlling for previous hourly wages instead.

covariates, the difference in wage offers between blacks and whites in the NJ UI data equals $-.160$ log points, or 14.7%, and is statistically highly significant. Thus, if the assumptions in Proposition 1 hold, then we estimate a lower bound on the impact of discrimination of almost 40% of the raw gap.²⁵

In order to demonstrate that this result is not an artifact of our data from the state of New Jersey, Table 3A present estimates similar to those in Table 2 obtained from the nationally representative Displaced Workers Survey (DWS) – a biannual supplement to the CPS administered to workers who lost their job during the previous three years; and Table 3B does so for the NLSY79.²⁶ Although low response rates and selective attrition are less of a concern in these data, we do not observe wage offers, and must therefore rely on accepted wages instead. Reassuringly, the same basic pattern as in the NJ UI data emerges. Controlling for earnings on the respondent’s previous job substantially reduces racial disparities, but the black-white gap remains statistically significant and economically large—approximately 15.6% in the DWS and about 8% in the NLSY79.²⁷ The latter estimate is remarkably close to that in Neal and Johnson (1996), but its interpretation is very different. While Neal and Johnson (1996) argue that their estimates of the residual black-white wage gap likely overstates the extent of labor market discrimination, under assumptions (i) and (ii) above the point estimate in this paper represents a *lower* bound.

As an additional robustness check, Table C.1 in the appendix explores the sensitivity of our results across a variety of specifications. Column (1) contains our main result and is identical to column (5) of Table 2. Column (2) adds a quadratic in previous wage as an additional covariate. The third column alters the outcome to be the best offer an individual receives (rather than including all offers), and we investigate racial differences in accepted (rather than offered) wages in column (4). Our next specification check uses the nearest neighbor matching estimator in Abadie and Imbens (2002), which provides a more flexible way of controlling for our set of covariates. In column (6), we allow β to differ by race and estimate the racial gap by assuming that blacks have white coefficients (Oaxaca 1973). Across these specifications, the results are similar, but large standard errors make inference challenging. The black coefficient ranges from $-.227$ (.031) for the matching estimator to $-.107$ (.068) when we use accepted wage. In half the cases, imprecision prohibits us

²⁵Lang and Manove (2011) find almost no racial differences in wages at the top of the skill distribution. While we have tried interacting previous earnings with race, our results are not precise enough to draw any conclusions about whether racial differences in offered wages are smaller or larger among previously highly paid individuals.

²⁶See Appendix B for a description of these data.

²⁷Our specifications using the NSLY79 also control for AFQT scores. The fact that we still observe sizable differences by race rules out the possibility that our results are driven by the possibility that less skilled workers suffer greater wage penalties upon losing their jobs and that skill is negatively correlated with being black.

from distinguishing the coefficient on our robustness tests from zero or the baseline result in column (1).

Finally, one might be worried that our results are driven by measurement error or mean reversion in wages.²⁸ A simple way to address this issue is to restrict the coefficient on previous wage to equal one. If measurement error or mean reversion were, indeed, driving our results one would expect the coefficient on race in this specification to equal zero. The result is presented in column (7). The coefficient on black decreases 0.049 log points (to -0.111) and the standard error increases by more than 50% which leaves the black coefficient economically large but statistically insignificant. It is unclear whether the differences between column (1) and column (7) of Table C.1 are due to true measurement error in the wages reported to the New Jersey Department of Labor and Workforce Development or to imposing restrictions on the data that are not warranted.²⁹

5.2 A Partial Test of the Identifying Assumptions

In this subsection we turn to the assumptions in Proposition 1. Recall, for our empirical approach to identify a lower bound on the impact of discrimination – be it statistical or taste-based – it needs to be the case that (i) blacks and whites do not systematically differ in their search behavior, search intensity, discount rates, the markets in which they search, and so on, i.e. $\text{Cov}(Race_i, \nu_{i,j}) = 0$; and (ii) previous wages do not systematically overstate blacks’ true ability, i.e. $\text{Cov}(Race_i, u_i) \geq 0$.

Assumption (ii) is not directly testable with our data. If previous wage equals marginal product, then this assumption holds and our approach will correctly identify racial discrimination. If previous wage is a function of both productivity and differential treatment by race, then our approach will provide a *lower* bound on the impact of discrimination. Conversely, if previous wage captures marginal product plus a diversity preference, the effect of affirmative action, or significant measurement error in wages (e.g., mean reversion, unmeasured amenities, and so on), then assumption two is violated and we will overstate the amount of discrimination in the market.³⁰

²⁸We are grateful to Joseph Altonji and David Card for making this point.

²⁹A further test of our approach is to see whether variables known to influence wages but are not related to information have a coefficient close to zero after controlling for previous earnings. One such variable is age. While age is an important predictor of wages in columns (1)-(3) of Table 2, once we control for previous wage the coefficients on age and its square are nearly zero and relatively precisely estimated. A similar pattern can be observed with respect to being married. This is not the case for our measures of educational attainment. Note, however, that if the market possesses more information about college than high school graduates (see Arcidiacono et al. 2010 for some evidence), then one might expect there to be wage differentials by educational attainment, even conditional on previous wage. The fact that the coefficients on educational attainment do decline, but don’t fall to zero after controlling for previous earnings, is thus consistent with a model of statistical discrimination. We are grateful to Kevin Lang and an anonymous referee for pointing this out to us.

³⁰It is unlikely that diversity preferences or affirmative action can explain our results, as our estimates are signifi-

By contrast, assumption (i) *is* testable. Guided by the model in Section 3, we explore five plausible violations of this assumption: spatial mismatch, racial differences in search behavior, search strategies, bargaining, as well as discount rates. On a purely descriptive level, the results below constitute one of the first analyses of racial differences in job finding (for complementary evidence based on the the same data set see Pager and Pedulla 2012).

Spatial Mismatch

Table 4 probes whether differences in the geographic location of blacks and whites across New Jersey can explain the estimated wage gaps (e.g., Cutler and Glaeser 1997, Jencks and Mayer 1990, Kain 1968, Holzer 1991). For instance, if blacks live in blighted neighborhoods with few high paying jobs, then this may lead them to draw wage offers from a different set of firms, and reconcile why, even conditional on previous earnings, they are offered lower wages. While a priori plausible – particularly during a period of mass unemployment such as the 2009 recession – the spatial mismatch theory receives only scant support in the data.

We test for the impact of spatial mismatch in two ways. First, we control for the distance that respondents report traveling to search for a job to proxy for searching in similar markets (recall, we also include industry fixed effects). Second, we include metropolitan area fixed effects. In both cases, the coefficient on black is not greatly affected – adding controls for distance traveled to search increases the coefficient on black to $-.179$ (.057) and adding fixed effects reduces it to $-.152$ (.065).

Search Intensity

Next, we turn to racial differences in search behavior. Table 5 displays estimates of equation (7) in which the outcome variable has been replaced with proxies of search intensity. These include: whether a respondent was actively looking for a job within the last week, the total number of hours she spent searching along with twelve categories detailing how they spent their time, the number of jobs applied to, and whether she received any job offer. For each outcome we estimate “raw” racial differences accounting only for gender and age (left columns), as well as gaps controlling for the full set of covariates including previous earnings (right columns).

Taking the point estimates at face value, blacks are 2.7 percentage points more likely to be looking for work during the last seven days, spend 1.5 hours more per week searching, write an

cantly larger than conventional estimates of the impact of Title VII of the Civil Rights Act, affirmative action, or the Civil Rights Act of 1991 (e.g., Ashenfelter and Heckman 1976, Heckman and Payner 1989, Chay 1998, Leonard 1984a, 1984b, 1990, and Smith and Welch 1984, among others). While some industries have seen large relative improvements of blacks, in particular with respect to employment (see Heckman and Payner 1989 or McCrary 2007), the impact of affirmative action on the labor market as a whole has been much more limited.

additional 1.3 applications, and are consequently about 2 percentage point more likely to receive a job offer. Although these differences are in most cases not very precisely estimated, we are able to rule out moderately sized gaps in favor of whites. Interestingly, blacks are significantly more likely to report contacting employers directly, contacting public employment agencies, and using informal networks. Thus, if anything, unemployed blacks appear to search more intensely for work across a variety of channels and generate more offers than their white counterparts.

Search Strategies

Racial differences in search strategies are investigated in Table 6. For the sake of brevity we restrict attention to six outcomes: whether the respondent did not apply to a job ad she saw within the last seven days, whether she didn't apply because the job was too far away, whether she applied to any white collar jobs, any blue collar ones, or any service jobs, and whether she accepted an offer.³¹

Broadly summarizing, the evidence in Table 6 does not reveal significant differences in search strategies between blacks and whites. For instance, blacks appear to be only slightly more likely than whites to ignore job ads, and are even less likely than whites to do so due to transportation difficulties. Moreover, after controlling for a host of individual characteristics (including previous earnings and previous industry) there are almost no differences in the types of jobs to which blacks and whites apply, although in the raw data blacks are significantly less likely to apply to white collar jobs. There is one exception however. Blacks are estimated to be more likely to accept an offer in hand—even after controlling for previous wages. Although this difference is non-trivial in magnitude, it is not statistically significant due to large standard errors.

Bargaining and Discount Rates

Estimates of racial differences in bargaining and a proxy for discount rates are presented in Table 7. The two columns on the left show that after adjusting for only age and gender, blacks are approximately 11 percentage points less likely to negotiate wages conditional on being offered a job. Yet, upon including our full set of covariates this difference halves and becomes statistically insignificant.

As part of the initial survey, respondents were asked whether they prefer to receive a \$20 Visa gift card within a few days or a \$40 one in 12 weeks. The two columns on the right of Table 7

³¹Results from other variables that proxy for search strategies are available from the authors upon request.

uses respondents’ actual choice as an admittedly crude proxy for discount rates.³² As evidenced by point estimates of 22 and 15.6 percentage points, blacks are substantially more likely than whites to opt for \$20 now—suggesting that differences in time preferences may explain part of the gap, at least if employers take these into account when making job offers.³³

Understanding the Impact of Search Strategies, Search Intensity, Bargaining, and Discount Rates

Table 8 provides a concise summary of the effect of each of the five potential violations of assumption (i). The estimates shown in the table correspond to the coefficient on $Race_i$, i.e. Γ in specification (7), and denote racial differences in offered wages relative to whites. If assumption (i) does indeed hold, then adding additional controls for each of the outcomes investigated above should not decrease the gap in a statistically meaningful way.

The first column displays racial differences after accounting for the set of covariates used in Table 2. Each subsequent column controls for one or more of the different dimensions of search behavior explored in Tables 4–7. For instance, the second column also includes controls for whether the respondent was looking for work during the last week, how many hours she spent searching, and the number of applications she wrote. The third column adds indicator variables for whether she didn’t apply to any job ad she saw within the last week, whether she did so because the job was too far away, as well as whether she applied to a job opening in any of 22 Standard Occupational Classification (SOC) Major Groups.

Despite the richness of the included covariates, the residual black-white difference in wage offers remains almost unaffected. Separately accounting for the effect of search intensity, search strategies, bargaining, time preferences, or geographic location reduces the gap by at most .033 log points—compared to a standard error of .060. Even after jointly controlling for all of these factors, job offers to blacks are still estimated to be .160 log points lower than those to observationally equivalent whites.³⁴

In sum, under the identifying assumptions of Proposition 1, we can conclude that discrimination accounts for at least one third of the black-white wage gap.

³²It is not entirely clear whether the choice between a \$20 gift card within a few days or a \$40 dollar one in 12 weeks elicits only time preferences, or whether issues of trust etc. also play a role—despite reassurance that the respondent would receive the gift card even if he didn’t participate in any of the follow-up surveys.

³³Note, however, that such behavior might in itself be considered discriminatory.

³⁴This difference is strikingly similar in size to that reported in Lang and Manove (2011) for the NLSY79 after controlling for education *and* AFQT.

6 Evidence Consistent with a Search-Matching Model

Recall, the finding from our empirical test are independent of whether discrimination is statistical or animus based. We argue, however, that the search-matching model in Section 3 constitutes a natural way to rationalize the data.

As explained above, there are several ways to introduce racial differences into this framework. If, for instance, blacks are on average less skilled than whites, i.e. $\mu_W > \mu_B$ (as documented by Neal and Johnson 1996, among others), then group membership constitutes a valuable signal of ability, and unemployed black workers will be offered lower initial wages than equally qualified whites. In symbols, $E[\omega_W] > E[\omega_B]$.

Our model provides three additional predictions, which distinguish it from a number of alternative theories. First, similar to Black (1995), statistical discrimination in a search framework yields a lower reservation wage for the disadvantaged group. Second, our model predicts the black-white wage gap to narrow with tenure in the firm. Third, if blacks are significantly more likely than whites to experience separations (as argued in Kletzer 1998), then aggregate wage gaps across firms will increase with labor market experience. Below, we explore the extent to which these predictions are borne out in the data.

Racial Differences in Reservation Wages

Table 9 presents evidence on racial differences in reservation wages (see Holzer 1986 for earlier evidence).³⁵ Reservation wages are gleaned from a question which asks, “Suppose someone offered you a job today, what is the lowest wage or salary you would accept (before deductions) for the type of work you are looking for.”³⁶

The first column in Table 9 shows that, after accounting for age and gender, blacks are willing to accept substantially lower offers than whites. The gap in reservation wages with these baseline controls equals $-.232$ log points. Accounting for educational achievement reduces the difference to $-.160$ log points, but it remains statistically significant. Similar to wage offers, earnings on the previous job are a very good predictor of reservation wages. Moving from the second to the third column R^2 increases from .323 to .549, and reduces the black coefficient to $-.067$ (.028).

³⁵It is important to note that differences in reservation wages need not necessarily be due to discriminatory hiring practices. Instead, they might simply reflect racial differences in discount rates or savings that could be used to smooth consumption while unemployed (Chetty 2008).

³⁶Krueger and Mueller (2011) report that whites are more likely than blacks to accept wage offers below their stated reservation wage, which could be due to a variety of factors such as misinterpretation of the survey question or individuals adjusting their reservation wage as they search.

Put differently, on average, blacks are willing to accept almost 7% lower wages than whites who previously earned just as much. Adding additional controls for the duration of unemployment, the reason the last job ended, or previous industry fixed effects, does little to alter this result.

Returns to Tenure Within Firms

In our model, blacks having lower mean pre-market skill results in lower intermediate stage wages for blacks. Over time, however, employers learn workers' true marginal product which results in no wage differences among equally productive tenured individuals. This provides a testable prediction: within the firm, racial differences in wages should narrow with tenure.

Empirical evidence in support of this prediction is presented in Table 10 (see also Goldsmith et al. 2006). Using the NJ UI data the table displays estimates of our empirical specification in which the outcome variable has been replaced by the natural logarithm of previous earnings. Additionally, we control for tenure on the previous job and interact it with race. As predicted, wages rise with tenure for all racial groups. More importantly, however, blacks have a 1.1 percentage points higher return to tenure than whites. Not only does the black-white difference in the return to tenure carry the expected sign, it is also highly statistically significant.

A potential confounding factor of the above approach is that blacks are more likely than whites to have short tenure and, as Topel (1991) shows, the returns to tenure are heavily weighted to the first years on a job. Thus, the above analysis could be confusing non-linearities in the returns to tenure as evidence in favor of the model. To test this possibility we re-estimate the model in Table 10 on various subsamples of the data. The results are shown in Appendix Table C.9. For comparison column (1) displays the baseline findings from Table 10. Column (2) excludes all individuals with less than two years of tenure, and column (3) does so for workers who had been with their previous employer for more than ten years. Lastly, column (4) excludes both of these groups. Reading across columns the interaction term becomes, if anything, larger (but is less precisely estimated), which lets us rule out this concern.

Aggregate Racial Gaps Across Firms

In stark contrast to the previous discussion, when workers who have been with the same firm for a considerable time lose their job, the black-white wage gap re-emerges as these workers are matched with a new firm. Thus, if blacks are sufficiently more likely than whites to incur a separation, the black-white wage gap will increase with labor market experience. Altonji and Pierret (2001) demonstrate that racial differences are small when workers just enter the labor market, but widen

with potential experience (see also Oettinger 1996).

Table 11 augments Altonji and Pierret’s (2001) original analysis of the NLSY79. Using data for the time period from 1979–92, columns (1)–(4) replicate the upper panel of their Table 1.³⁷ The negative coefficient on the interaction term between black and potential experience indicates that the black-white wage widens by roughly 1% per year of experience.

In column (5) we extend Altonji and Pierret (2001) by adding tenure and its interaction with race to the set of covariates. As predicted by our theory, blacks experience a 1.1 percentage points *higher* return to tenure than whites. Not only is the difference statistically significant, it is also strikingly close to our estimate from the NJ UI data. The remainder of the table shows that this result is robust to including additional years of data, and does not depend on Altonji and Pierret’s (2001) choice to control for a cubic time trend interacted with black. Although the black-white wage gap increases as individuals change employers and accumulate labor market experience, it is estimated to be substantially smaller among those who have been with the same firm for a long time.

7 Discussion

To conclude our analysis, we explore the extent to which discrimination based on animus or differences in pre-market skills can account for our set of facts: (1) blacks incur larger losses than whites with job separations; (2) blacks have lower reservation wages; and (3) blacks garner higher returns to tenure in a firm.

Taste-Based Discrimination

Discriminatory tastes of employers, co-workers, or customers can give rise to black-white wage differences (Becker 1957). If, for instance, some fraction of employers incurs disutility from interacting with black workers, then the wage offered to blacks must be lower than that of whites in order for the employer to be indifferent. In equilibrium, the marginal discriminator determines the black-white wage gap. Similar arguments apply when customers or co-workers discriminate based on animus.³⁸

³⁷The total number of observations in Altonji and Pierret (2001) is 21,058 while that in our sample is 21,026. This small difference is due to missing information on wages in the work history file of the NLSY79. Nevertheless, our estimates are almost identical to theirs. For a detailed description of the sample construction procedures see Appendix B, or the Data Appendix in Altonji and Pierret (2001).

³⁸In a rare empirical test of this theory Charles and Guryan (2008) argue that animus accounts for about one quarter of the observed black-white wage gap.

Traditional models of taste-based discrimination can rationalize equilibrium wage gaps, but have difficulty explaining why, after losing their job, blacks are offered lower wages than previously equally well paid whites. Unless the marginal discriminator changes during the year our data were collected, controlling for previous earnings should eliminate the black-white wage gap – even in a world where taste-based discrimination is present. This is inconsistent with what we find in the data.

In contrast to neoclassical models of the labor market, models that include search frictions, such as Black (1995), predict that minorities will, on average, be paid lower wages as long as *any* discriminatory employer is in the market. Expecting discrimination, blacks have lower reservation wages than whites. Moreover, in a world in which blacks invest more in firm specific human capital than whites the former have higher returns to tenure and incur larger losses from job separations. The key to this explanation is that blacks matched with a non-discriminatory employer may have more of an incentive to invest in firm specific human capital, as the market provides less insurance than it does for equally skilled whites.³⁹ Thus, depending on whether blacks do, in fact, invest more in firm specific human capital than whites, our set of facts may also be consistent with a taste-based model of discrimination that features search frictions.

Racial Differences in Pre-Market Factors

A separate strand of the literature relies on disparities in pre-market factors such as education and skill to explain racial wage gaps.⁴⁰ For instance, O’Neill (1990) as well as Neal and Johnson (1996) show that after controlling for AFQT scores—which presumably measure skill prior to entry into the labor market—the black-white wage difference in the NLSY79 narrows substantially or even reverses. This theory finds mixed support in our data.

Racial differences in pre-market factors can explain racial differences in reservation wages. And, to the extent that the price of skill increases with labor market experience or skill gaps widen with labor market experience, then racial differences in pre-market factors can also explain why aggregate wage gaps increase with age. Indeed, Altonji and Pierret (2001) demonstrate that the importance of AFQT increases with labor market experience (see Table 11).

To explain why blacks incur a higher wage penalty from job separations than whites, one must

³⁹Of course, blacks might acquire more firm specific human capital than whites for reasons other than discrimination. Hu and Taber (2011), for instance, present a model in which different types of workers simply perform different tasks.

⁴⁰It is theoretically unclear whether disparities in pre-market factors cause racial wage gaps, or whether the latter lead minorities to invest less and thereby cause the former (see Lundberg and Startz 1983, or Coate and Loury 1993 for equilibrium analyses).

assume that there is a significant amount of firm specific investment among workers with low pre-market skills. Moreover, a pre-market theory predicts that, conditional on AFQT, there are no racial differences in the returns to tenure. This prediction is at odds with the data. Columns (7) and (8) in Table 11 reveal that, conditional AFQT, blacks have significantly higher returns to tenure than whites. Without controlling for AFQT, blacks have 1.1 percentage point higher returns to tenure. Accounting for AFQT *increases* the coefficient to 1.2 percentage points.⁴¹ Given these data, it is unlikely that pre-market factors alone explain the patterns in our data; although racial differences in pre-market factors are important determinants of black-white inequality, and may even *give rise* to statistical discrimination.

A Note on Statistical Discrimination and the Return to Education

Neal (2006) describes an important critique regarding the empirical content of models of statistical discrimination, as developed by Arrow (1973) and Coate and Loury (1993). In these models, blacks anticipate discrimination in the labor market and, expecting this, invest less in skills than whites. Empirically, however, many have shown that the return to investment in skills is, if anything, higher for blacks than whites which is inconsistent with simple versions of the theory (e.g., see Neal and Johnson 1996).

While we do not explicitly model investment in skills, there are several viable ways to incorporate this critique into our theory. Generally, it is important to note that the return to education is determined at the margin. That is, just because statistical discrimination causes blacks to earn on average lower wages, does not necessarily mean that the function mapping educational investment into earnings must be flatter. In equilibrium it will be the case that the gross return on investment equals individuals' opportunity cost (Becker 1962, 1993). Hence, if blacks are more likely to be cash constrained or face higher cost of investing, then this alone may give rise to statistical discrimination *and* explain higher estimated payoffs—assuming decreasing marginal returns.

Moreover, blacks may experience weakly higher returns on investment if education reduces the variance in the signal to employers (for empirical evidence see Arcidiacono et al. 2010); which is, in fact, the assumption that drives the model in Lang and Manove (2011). In their analysis blacks “overinvest” in education to signal their (unobserved) ability. If μ depends not only on group investments, but also on environmental factors such as school or neighborhood quality, then in equilibrium it might well be the case that $\mu_B < \mu_W$, despite higher returns for blacks.

⁴¹ Accounting for non-linearities in the returns to tenure by including years on the job in four categories, does not alter this result.

An alternative way to rationalize higher returns for blacks is to assume that educational attainment decreases the probability of job loss (e.g., Kletzer 1998). In this case blacks would experience a higher return to education than whites because it shields them from costly job losses.

The racial wage gap is a robust empirical regularity. Simple comparisons of mean wages typically find black-white wage differences in excess of 30%. While there exists almost unanimous consensus that differences in formal schooling and pre-market skill are important determinants of the observed disparities, the extent to which discrimination contributes to the gap remains one of the most debated issues in the social sciences.

In this paper we develop a novel test for the presence of discrimination using a newly available data set. Results from this test suggest that the impact of racial discrimination on offered wages is at least one third of the raw black-white wage gap in our data – subject to our identifying assumptions.

Taking our estimates at face value, labor market discrimination appears to be an impediment to racial income equality. This suggests that alleviating racial inequality may take a combination of policies to both eliminate barriers to investing in education and other premarket skills as well as anti-discrimination enforcement so that minorities are rewarded for those skills.

A Technical Appendix

In this appendix, we provide formal proofs for the results stated in the main text.

Proof of Proposition 1. Replacing θ_i in (6) with $\theta_i = \mu + \lambda \ln(w_i) + X_i' \zeta + u_i$ yields the estimable specification

$$\ln(\omega_{i,j}) = (\kappa_0 + \alpha_0 \mu) + Race_i' \Gamma_0 + X_i' (\beta_0 + \alpha_0 \zeta) + \alpha_0 \lambda \ln(w_i) + (\alpha_0 u_i + \nu_{i,j}),$$

in which only $(\alpha_0 u_i + \nu_{i,j})$ is not observed by the econometrician.

The Frisch-Waugh Theorem (Frisch and Waugh 1933) implies that

$$\text{plim } \widehat{\Gamma}_{OLS} = \Gamma_0 + \frac{\text{Cov}(\widetilde{Race}_i, \alpha_0 u_i + \nu_{i,j})}{\text{Var}(\widetilde{Race}_i)},$$

where \widetilde{Race}_i denotes the residual from projecting $Race_i$ onto X_i , $\ln(w_i)$, and a constant. Since $\text{Var}(\widetilde{Race}_i) > 0$, it suffices to show that $\text{Cov}(\widetilde{Race}_i, \alpha_0 u_i + \nu_{i,j}) \geq 0$.

From the definition of \widetilde{Race}_i and using the Frisch-Waugh Theorem again one obtains:

$$\text{Cov}(\widetilde{Race}_i, \alpha_0 u_i + \nu_{i,j}) = \text{Cov}\left(Race_i - \chi - X_i' \frac{\text{Cov}(Race_i, \widetilde{X}_i)}{\text{Var}(\widetilde{X}_i)} - \frac{\text{Cov}(Race_i, \widetilde{\ln(w_i)})}{\text{Var}(\widetilde{\ln(w_i)})} \ln(w_i), \alpha_0 u_i + \nu_{i,j}\right),$$

where $\chi \equiv E[Race_i] - E[X_i'] \frac{\text{Cov}(Race_i, \widetilde{X}_i)}{\text{Var}(\widetilde{X}_i)} - \frac{\text{Cov}(Race_i, \widetilde{\ln(w_i)})}{\text{Var}(\widetilde{\ln(w_i)})} E[\ln(w_i)]$, and \widetilde{X}_i ($\widetilde{\ln(w_i)}$) corresponds to the residual from projecting X_i ($\ln(w_i)$) onto $\ln(w_i)$ (X_i) and a constant. Since $X_i \perp (u_i, \nu_{i,j})$ as well as $\ln(w_i) \perp (u_i, \nu_{i,j})$, we have that $\text{Cov}(\widetilde{Race}_i, \alpha_0 u_i + \nu_{i,j}) = \text{Cov}(Race_i, \alpha_0 u_i + \nu_{i,j})$. Assumptions (i) and (ii) in Proposition 1 ensure that $\text{Cov}(Race_i, \alpha_0 u_i + \nu_{i,j}) \geq 0$. Hence, $\text{plim } \widehat{\Gamma}_{OLS} \geq \Gamma_0$, as desired. ■

Proposition 2 *The sequence of reservation wages is increasing, i.e. $\theta^* > \omega^*$.*

Proof. Note that $\Pr[\theta > \theta^* | \theta + \xi] > 0$ and $J(\theta) \geq Q$ with the inequality being strict for $\theta > \theta^*$.

It then follows that

$$\omega^* + \beta \int J(s) dF(s | \omega^*, \sigma_{\theta|\theta+\xi}^2) > \omega^* + \beta Q.$$

Hence, equation (4) implies $\omega^* < (1 - \beta) Q$. Recognizing that $\theta^* = (1 - \beta) Q$ by (2) completes the proof. ■

Proposition 3 *On average wages increase with tenure in the firm. That is, $E[\omega|\omega > \omega^*] < E[\theta|\theta > \theta^*, \omega > \omega^*]$.*

Proof. For completeness we reproduce the proof contained in Sargent (1987, pp. 79).

First, note that the mean wage of previously unemployed workers is given by

$$E[\omega|\omega > \omega^*] \equiv \bar{\omega} = \frac{\int_{\omega^*}^{\infty} \omega dG(\omega|\mu, \sigma_{\omega}^2)}{\int_{\omega^*}^{\infty} dG(\omega|\mu, \sigma_{\omega}^2)},$$

and that of tenured workers equals

$$E[\theta|\theta > \theta^*, \omega > \omega^*] \equiv \bar{\theta} = \frac{\int_{\omega^*}^{\infty} \int_{\theta^*}^{\infty} \theta dF(\theta|\omega, \sigma_{\theta|\theta+\xi}^2) dG(\omega|\mu, \sigma_{\omega}^2)}{\int_{\omega^*}^{\infty} \int_{\theta^*}^{\infty} dF(\theta|\omega, \sigma_{\theta|\theta+\xi}^2) dG(\omega|\mu, \sigma_{\omega}^2)}.$$

From the standard properties of normally distributed random variables it follows that

$$\bar{\omega} = \mu + \sigma_{\omega} \frac{\phi\left(\frac{\mu - \omega^*}{\sigma_{\omega}}\right)}{\Phi\left(\frac{\mu - \omega^*}{\sigma_{\omega}}\right)}.$$

Moreover, since $\int_{\theta^*}^{\infty} dF(\theta|\omega, \sigma_{\theta|\theta+\xi}^2) = \Phi\left(\frac{\omega - \theta^*}{\sigma_{\theta|\theta+\xi}}\right)$, we also have that

$$\int_{\theta^*}^{\infty} \theta dF(\theta|\omega, \sigma_{\theta|\theta+\xi}^2) = \omega \Phi\left(\frac{\omega - \theta^*}{\sigma_{\theta|\theta+\xi}}\right) + \sigma_{\theta|\theta+\xi} \phi\left(\frac{\omega - \theta^*}{\sigma_{\theta|\theta+\xi}}\right) > \omega \Phi\left(\frac{\omega - \theta^*}{\sigma_{\theta|\theta+\xi}}\right).$$

This implies

$$\bar{\theta} > \frac{\int_{\omega^*}^{\infty} \omega \Phi\left(\frac{\omega - \theta^*}{\sigma_{\theta|\theta+\xi}}\right) dG(\omega|\mu, \sigma_{\omega}^2)}{\int_{\omega^*}^{\infty} \Phi\left(\frac{\omega - \theta^*}{\sigma_{\theta|\theta+\xi}}\right) dG(\omega|\mu, \sigma_{\omega}^2)} \equiv \tilde{\theta}.$$

Hence, it suffices to show that $\tilde{\theta} \geq \bar{\omega}$.

Next, let $g(\omega|\mu, \sigma_{\omega}^2)$ denote the probability density function associated with $G(\omega|\mu, \sigma_{\omega}^2)$, and note that the density of observed wages in the second stage is given by:

$$\tilde{g}(\omega|\mu, \sigma_{\omega}^2) = \begin{cases} \frac{g(\omega|\mu, \sigma_{\omega}^2)}{\int_{\omega^*}^{\infty} dG(s|\mu, \sigma_{\omega}^2)} & \text{if } \omega \geq \omega^* \\ 0 & \text{if } \omega < \omega^* \end{cases}.$$

Similarly, define

$$\tilde{g}(\omega|\mu, \sigma_\omega^2) = \begin{cases} \frac{\Phi\left(\frac{\omega-\theta^*}{\sigma_{\theta|\theta+\xi}}\right)g(\omega|\mu, \sigma_\omega^2)}{\int_{\omega^*}^{\infty} \Phi\left(\frac{s-\theta^*}{\sigma_{\theta|\theta+\xi}}\right) dG(s|\mu, \sigma_\omega^2)} & \text{if } \omega \geq \omega^* \\ 0 & \text{if } \omega < \omega^* \end{cases},$$

and let $\tilde{G}(\omega|\mu, \sigma_\omega^2)$ and $\tilde{\tilde{G}}(\omega|\mu, \sigma_\omega^2)$ denote the cumulative distribution functions associated with $\tilde{g}(\omega|\mu, \sigma_\omega^2)$ and $\tilde{\tilde{g}}(\omega|\mu, \sigma_\omega^2)$, respectively.

By construction,

$$\bar{\omega} = \int_{\omega^*}^{\infty} \omega d\tilde{G}(\omega|\mu, \sigma_\omega^2) = \omega^* + \int_{\omega^*}^{\infty} 1 - \tilde{G}(\omega|\mu, \sigma_\omega^2) d\omega \quad (8)$$

$$\tilde{\theta} = \int_{\omega^*}^{\infty} \omega d\tilde{\tilde{G}}(\omega|\mu, \sigma_\omega^2) = \omega^* + \int_{\omega^*}^{\infty} 1 - \tilde{\tilde{G}}(\omega|\mu, \sigma_\omega^2) d\omega \quad (9)$$

as well as

$$\tilde{\tilde{g}}(\omega|\mu, \sigma_\omega^2) = \frac{\Phi\left(\frac{\omega-\theta^*}{\sigma_{\theta|\theta+\xi}}\right) \int_{\omega^*}^{\infty} dG(s|\mu, \sigma_\omega^2)}{\int_{\omega^*}^{\infty} \Phi\left(\frac{s-\theta^*}{\sigma_{\theta|\theta+\xi}}\right) dG(s|\mu, \sigma_\omega^2)} \tilde{g}(\omega|\mu, \sigma_\omega^2).$$

As, for $\theta^* > -\infty$, $\Phi\left(\frac{\omega-\theta^*}{\sigma_{\theta|\theta+\xi}}\right)$ is strictly increasing in ω and both $\tilde{\tilde{g}}(\omega|\mu, \sigma_\omega^2)$ and $\tilde{g}(\omega|\mu, \sigma_\omega^2)$ are probability densities, it must be the case that there exists exactly one $\omega' > \omega^*$ such that $\tilde{\tilde{g}}(\omega|\mu, \sigma_\omega^2) \geq \tilde{g}(\omega|\mu, \sigma_\omega^2)$ whenever $\omega \geq \omega'$. To see this note that $\int_{\omega^*}^{\infty} dG(s|\mu, \sigma_\omega^2) > \int_{\omega^*}^{\infty} \Phi\left(\frac{s-\theta^*}{\sigma_{\theta|\theta+\xi}}\right) dG(s|\mu, \sigma_\omega^2)$ and that $0 \leq \Phi\left(\frac{\omega-\theta^*}{\sigma_{\theta|\theta+\xi}}\right) \leq 1$. Thus, $\tilde{g}(\omega|\mu, \sigma_\omega^2) < \tilde{\tilde{g}}(\omega|\mu, \sigma_\omega^2)$ for sufficiently large ω . Also, recall that $\tilde{g}(\omega''|\mu, \sigma_\omega^2) = \tilde{\tilde{g}}(\omega''|\mu, \sigma_\omega^2) = 0$ for $\omega < \omega^*$. The fact that $\Phi\left(\frac{\omega-\theta^*}{\sigma_{\theta|\theta+\xi}}\right)$ is strictly increasing implies that $\frac{\tilde{\tilde{g}}(\omega|\mu, \sigma_\omega^2)}{\tilde{g}(\omega|\mu, \sigma_\omega^2)}$ is strictly increasing as well (for $\omega \geq \omega^*$). Since both densities have to integrate up to one, we have that $\tilde{g}(\omega^*|\mu, \sigma_\omega^2) > \tilde{\tilde{g}}(\omega^*|\mu, \sigma_\omega^2)$ and that the density functions cross only once.

Therefore, $\tilde{\tilde{G}}(\omega|\mu, \sigma_\omega^2) < \tilde{G}(\omega|\mu, \sigma_\omega^2)$ for $\omega > \omega'$. From (8) and (9) it then follows that $\tilde{\theta} > \bar{\omega}$, which completes the proof. ■

Proposition 4 *Lower arrival rates result in lower reservation wages, i.e. $\frac{d\theta^*}{d\delta} > 0$.*

Proof. By (2) it suffices to show that $\frac{dQ}{d\delta} > 0$. Rearranging (5) and taking the derivative with respect to δ gives

$$\frac{dQ}{d\delta} = \frac{\beta(1-\beta)}{(1-\beta(1-\delta))^2} \int V(w) dG(w|\mu, \sigma_\omega^2) + \frac{\delta\beta}{1-\beta(1-\delta)} \frac{d}{d\delta} \int V(w) dG(w|\mu, \sigma_\omega^2). \quad (10)$$

From the definition of $V(\omega)$ it follows that, for all ω ,

$$\frac{dV(\omega)}{d\delta} \geq \min\left\{\beta \frac{d}{d\delta} \int J(s) dF\left(s|\omega, \sigma_{\theta|\theta+\xi}^2\right), \frac{dQ}{d\delta}\right\}; \quad (11)$$

and from equation (1) we have that

$$\frac{dJ(\theta)}{d\delta} \geq \min\left\{\frac{\alpha\beta}{1-\beta(1-\alpha)} \frac{dQ}{d\delta}, \frac{dQ}{d\delta}\right\}$$

for all θ .

CASE 1: Suppose $\frac{dQ}{d\delta} < 0$. Then, as $0 < \frac{\alpha\beta}{1-\beta(1-\alpha)} < 1$, $\frac{dJ(\theta)}{d\delta} \geq \frac{dQ}{d\delta}$. Thus, by (11) we have that $\frac{dV(\omega)}{d\delta} \geq \frac{dQ}{d\delta}$.

Since the distribution of ω is nondegenerate normal and agents can always refuse negative offers, $V(\omega) > 0$ for all ω . Therefore,

$$\frac{dQ}{d\delta} > \frac{\delta\beta}{1-\beta(1-\delta)} \frac{d}{d\delta} \int V(w) dG(w|\mu, \sigma_w^2) \geq \frac{\delta\beta}{1-\beta(1-\delta)} \frac{dQ}{d\delta}. \quad (12)$$

Letting $c \equiv \frac{\delta\beta}{1-\beta(1-\delta)}$ and rearranging (12) gives

$$(1-c) \frac{dQ}{d\delta} > 0,$$

which produces a contradiction, as $0 < c < 1$.

CASE 2: Suppose $\frac{dQ}{d\delta} \geq 0$. Then, $\frac{dJ(\theta)}{d\delta} \geq \frac{\alpha\beta}{1-\beta(1-\alpha)} \frac{dQ}{d\delta}$ and $\frac{dV(\omega)}{d\delta} \geq \frac{\alpha\beta^2}{1-\beta(1-\alpha)} \frac{dQ}{d\delta}$. In this case, equation (12) becomes

$$\frac{dQ}{d\delta} > \frac{\delta\beta}{1-\beta(1-\delta)} \frac{\alpha\beta^2}{1-\beta(1-\alpha)} \frac{dQ}{d\delta}.$$

Again, letting $c \equiv \frac{\delta\beta}{1-\beta(1-\delta)} \frac{\alpha\beta^2}{1-\beta(1-\alpha)}$ and rearranging gives

$$(1-c) \frac{dQ}{d\delta} > 0. \quad (13)$$

Note that $0 < c < 1$. Hence, (13) demonstrates that $\frac{dQ}{d\delta} > 0$, as desired. ■

Proposition 5 *A higher probability of job loss results in lower reservation wages, i.e. $\frac{d\theta^*}{d\alpha} < 0$.*

Proof. By (2) it suffices to show that $\frac{dQ}{d\alpha} < 0$. Rearranging (5) and taking the derivative with respect to α gives

$$\frac{dQ}{d\alpha} = \frac{\delta\beta}{1-\beta(1-\delta)} \frac{d}{d\alpha} \int V(w) dG(w|\mu, \sigma_\omega^2). \quad (14)$$

From the (3) we have that, for all ω ,

$$\frac{dV(\omega)}{d\alpha} \leq \max\left\{\beta \frac{d}{d\alpha} \int J(s) dF(s|\omega, \sigma_{\theta|\theta+\xi}^2), \frac{dQ}{d\alpha}\right\}; \quad (15)$$

and from the definition of J , i.e. $J(\theta) = \max\{\theta + \alpha\beta Q + (1-\alpha)\beta J(\theta), Q\}$, it follows that either

$$\frac{dJ(\theta)}{d\alpha} = \frac{\beta}{1-\beta(1-\alpha)} (Q - J(\theta)) + \frac{\alpha\beta}{1-\beta(1-\alpha)} \frac{dQ}{d\alpha} \quad (16)$$

or

$$\frac{dJ(\theta)}{d\alpha} = \frac{dQ}{d\alpha}.$$

Since $J(\theta) \geq Q$ for all θ , it must be the case that $\frac{dJ(\theta)}{d\alpha} \leq \max\left\{\frac{\alpha\beta}{1-\beta(1-\alpha)} \frac{dQ}{d\alpha}, \frac{dQ}{d\alpha}\right\}$.

CASE 1: Suppose $\frac{dQ}{d\alpha} > 0$. Then, as $0 < \frac{\alpha\beta}{1-\beta(1-\alpha)} < 1$, $\frac{dJ(\theta)}{d\alpha} \leq \frac{dQ}{d\alpha}$. Thus, by (15) we have that $\frac{dV(\omega)}{d\alpha} \leq \frac{dQ}{d\alpha}$.

This and (14) imply

$$\frac{dQ}{d\alpha} \leq \frac{\delta\beta}{1-\beta(1-\delta)} \frac{dQ}{d\alpha}. \quad (17)$$

Letting $c \equiv \frac{\delta\beta}{1-\beta(1-\delta)}$ and rearranging (17) gives

$$(1-c) \frac{dQ}{d\alpha} \leq 0,$$

which produces a contradiction, since $0 < c < 1$.

CASE 2: Suppose $\frac{dQ}{d\alpha} \leq 0$. Then, as $0 < \frac{\alpha\beta}{1-\beta(1-\alpha)} < 1$, $\frac{dJ(\theta)}{d\alpha} \leq \frac{\alpha\beta}{1-\beta(1-\alpha)} \frac{dQ}{d\alpha}$. Thus, by (15) we have that $\frac{dV(\omega)}{d\alpha} \leq \frac{\alpha\beta^2}{1-\beta(1-\alpha)} \frac{dQ}{d\alpha}$.

In this case equation (17) becomes

$$\frac{dQ}{d\alpha} \leq \frac{\delta\beta}{1-\beta(1-\delta)} \frac{\alpha\beta^2}{1-\beta(1-\alpha)} \frac{dQ}{d\alpha}.$$

Letting $c \equiv \frac{\delta\beta}{1-\beta(1-\delta)} \frac{\alpha\beta^2}{1-\beta(1-\alpha)}$ and rearranging gives

$$(1-c) \frac{dQ}{d\alpha} \leq 0. \quad (18)$$

Note that $0 < c < 1$. Hence, (18) demonstrates that $\frac{dQ}{d\alpha} \leq 0$.

It remains to be shown that $\frac{dQ}{d\alpha} \neq 0$. By way of contradiction, suppose $\frac{dQ}{d\alpha} = 0$. Then, $\frac{dJ(\theta)}{d\alpha} \leq 0$ with the inequality being strict for large enough θ (due to (16) and the fact that $J(\theta) > Q$ for large θ). From (3) we have that $\frac{dV(\omega)}{d\alpha} \leq 0$, again with the inequality being strict for ω large enough. This in connection with (14) implies that $\frac{dQ}{d\alpha} < 0$, which produces the desired contradiction. ■

B Data Appendix

B.1 NJ UI Data

The following description of the NJ UI data borrows heavily from Krueger and Mueller (2011). For a more detailed description of the data (in particular of the sampling procedures, the survey instrument, or details of the implementation) the interested reader should consult their appendix.

During the fall of 2009 and early 2010 the Princeton University Survey Research Center (PSRC) collected high-frequency longitudinal information on the unemployed in the state of New Jersey. Starting from a complete list of the approximately 360,000 individuals receiving unemployment insurance (UI) as of September 28, 2009, PSRC drew a stratified random sample of 63,813 individuals—oversampling the long-term unemployed. The sampled population was then contacted by the New Jersey Department of Labor and Workforce Development (LWD) and invited (by email or letter) to participate in a confidential web survey for a period of 12 consecutive weeks. Individuals who were unemployed for 60 weeks or longer at the beginning of the survey were later asked to participate in an additional 12 weeks of interviewing—for a maximum of 24 weeks. In this paper, however, we restrict attention to the first 12 weeks for all respondents.

Six to ten days after the initial invitation, PSRC made almost 10,000 phone calls encouraging non-responders to participate in the survey. Two weeks thereafter the survey was closed for new participants. In order to remind respondents to participate in the weekly follow-up surveys e-mail invitations were sent out seven days after completion of the most recent online interview, but not on Sundays or Mondays.⁴²

As incentive to participate respondents could choose between a \$20 Visa gift card mailed to them within a few days, or a \$40 one sent out after the 12 week survey period—regardless of whether the respondent would complete any follow-up interviews.

⁴²This restriction was imposed so the time diary would pertain to a weekday. Respondents who completed their most recent survey on a Sunday would receive their invitation on Tuesday of the following week.

The actual survey consisted of an initial entry questionnaire and weekly follow-up interviews. The former elicited information on demographics, previous employment, asset holdings, and spouses' employment status; whereas the latter inquired about job search activities, time use, reservation wages, and job offers, among other topics. Participants were given the choice of receiving an incentive payment of \$20 within a few days of completing the entry questionnaire, or \$40 at the end of the 12 week survey period.

Unfortunately, only 6,025 of the sampled individuals participated in the entry wave of the survey, and those who responded to the initial interview completed only about 40 percent of weekly follow-ups. Moreover, participants were more educated, more likely to be female, and had higher previous earnings than the baseline population. Using rich administrative data, Krueger and Mueller (2011) create sampling weights in order to adjust for the stratified survey design as well as nonresponse. Comparing characteristics of respondents to the universe of UI recipients along a number of dimensions, they conclude that the low response rate did not significantly skew the sample on observables—even on those that were not used in calculating the weights. Throughout our analysis we use the weights created by Krueger and Mueller (2011). Moreover, we restrict attention to respondents with non-missing information on race who are not listed as previously self-employed. Our final sample consists of 5,251 individuals and 26,901 person-week observations.

The following variables are used throughout our analysis:

Race is a set of mutually exclusive indicator variables, i.e. White, Black, Hispanic, Asian, and Other Race, that denote a respondent's racial identification. In our regressions White serves as the omitted category.

Female is an indicator variable that equals one if the respondent is female and zero otherwise.

Age denotes the respondent's age in years.

Number of Children denotes the respondent's number of children. The variable is taken from the entry questionnaire which asked "How many children do you have?"

Marital Status is a set of mutually exclusive indicator variables, i.e. Single, Married, Divorced, Widowed, and Cohabiting But Not Married, that denote a respondent's marital status. The information is taken from the entry questionnaire which asked "What is your marital status?" The

set of possible answers was: “Single (Never Married)”, “Married”, “Divorced”, “Widowed”, and “Domestic partnership (living together but not married)”.

Educational Attainment is a set of mutually exclusive indicator variables, i.e. High School Dropout, High School Graduate, Some College, and College Graduate, that denote a respondent’s highest level of completed education. The information is taken from the entry questionnaire which asked “What is the highest level of education you have completed?” The set of possible answers was: “Some high school or less”, “High school diploma or equivalent”, “Some college”, “College diploma”, “Some graduate school”, “Graduate degree”. For the purposes of this paper we combine the last three answer choices into one category.

Weeks Unemployed denotes the duration of a respondent’s unemployment spell as of the time she filled out a weekly follow-up survey. The variable has been constructed using information on the time she lost her main job, i.e. the one at which she worked the most hours, from the entry questionnaire as well as on the time she filled out the weekly survey.

Previous Weekly Earnings denotes the respondent’s average weekly earnings during the past year. This variable has been constructed using administrative information from the New Jersey Department of Labor and Workforce Development on earnings and weeks worked in the base year. Following Krueger and Mueller (2011) we discard observation with weekly earnings of less than \$100 or more than \$8,000, and impute base year earnings of \$152,191 for those individuals subject to top-coding.

Tenure on Previous Job denotes the time (in years) that the respondent worked for her previous employer. The variable is taken from the entry questionnaire which asked “How many years had you worked for that employer when that job ended?”

Reason Last Job Ended is a set of mutually exclusive indicator variables, i.e. Quit Last Job, Laid Off from Last Job, and Last Job was Temporary, which denote why the respondent’s last job ended. The information is taken from the entry questionnaire which asked “Did you lose or quit that job, or was it a temporary job that ended?” The set of possible answers was: “Lost job”, “Quit Job”, and “Temporary Job ended”. In our regressions Laid Off from Last Job serves as the omitted category.

Previous Industry refers to a set of nine indicator variables categorizing the industry in which participants previously worked according to the North American Industry Classification System (NAICS).

Received Offer Last Week is an indicator variable for whether the respondent reports having received at least one job offer during the previous seven days. The variable is taken from the weekly follow-up surveys which asked “In the last 7 days, did you receive any job offers? If yes, how many?”

Offered Hourly Wage denotes the pay associated with the best job offer the respondent received within the last seven days, converted into an hourly rate. To construct this variable we use information from the weekly follow-up surveys which asked “What was the wage or salary offered (before deductions)? Is that per year, per month, bi-weekly, weekly or per hour?” and “How many hours a week would you have to work on that job?”. We discard observations with missing information on hours, and, following Krueger and Mueller (2011), observations with hourly offered wages of less than \$5 or more than \$100.

Accepted Job Offer in Hand is an indicator variable equal to one if the respondent accepted or thinks she will accept the best offer received within the last seven days. The variable is taken from the weekly follow-up surveys which asked “Have you accepted or do you think you will accept this job offer?” The set of possible answers was: “Yes”, “No”, “Don’t know yet”. Only respondents answering “Yes” are coded as one; those who say “Don’t know yet” are set to missing.

Accepted Hourly Wage denotes the hourly wage associated with job offered that the respondent accepted, if she in fact did accept one. The variable is coded in the same way as the two previous ones.

Looking for Job Last Week is an indicator variable equal to one if the respondent was actively looking for work during the previous seven days. The variable is taken from the weekly follow-up surveys which asked “Have you done anything to find work during the last 7 days?”.

Hours Spent Searching denotes the total number of hours the respondent claims to have spent trying to find a job. The variable is constructed using information from the weekly follow-up surveys which asked “On the previous page you indicated what kind of methods you used to find work.

In the last 7 days, about how many hours and minutes did you spend on each of those methods? Your best guess is okay.” The set of methods included: “Contacted employer directly”, “Contacted public employment agency”, “Contacted private employment agency”, “Contacted friends or relatives”, “Contacted school/university employment center”, “Checked union/professional registers”, “Attended job training programs/courses”, “Placed or answered ads”, “Went to interview”, “Sent out resumes/filled out applications,” “Looked at ads,” “Other”.

Number of Applications denotes the number of jobs to which the respondent applied within the last seven days. The variable is taken from the weekly follow-up surveys which asked “How many jobs did you apply to in the last 7 days?”

Didn’t Apply to Some Job Ad Last Week is an indicator variable equal to one if the respondent did not apply to any job for which she was qualified—for any reason. The variable is constructed using information from the weekly follow-up surveys which asked “What about jobs you did not apply for? Did you find or hear about any jobs in the last 7 days for which you are qualified but did not apply for?”

Didn’t Apply Since Too Far Away is an indicator variable equal to one if the respondent did not apply to any job for which she was qualified because it was too far away, and equal to zero if she did not apply for any other reason. The variable is constructed using information from the weekly follow-up surveys which asked “What about jobs you did not apply for? Did you find or hear about any jobs in the last 7 days for which you are qualified but did not apply for?” and “Why not? Please check all that apply.”

Applied to Any White Collar Job Last Week is an indicator variable equal to one if the respondent applied to a white collar job within the last seven days and zero otherwise. The variable has been constructed using information from the weekly follow-up surveys which asked “Please list the three most recent jobs you applied to in the last 7 days. If you applied to more than one of the same kind of job, list each job separately. (examples of job titles include: waiter, computer technician, warehouse worker, administrative assistant, etc.)” The answers in the text entry fields were then categorized into Standard Occupational Categories (SOC) by trained staff at the University of Wisconsin Survey Center. 97% of job titles could be successfully matched to 3-digit SOC codes. We code the following 2000 Major Groups as ‘white collar’: “Management”, “Business and Financial

Operations”, “Computer and Mathematical Occupations”, “Office and Administrative Support”, “Architecture and Engineering”, “Life, Physical, and Social Science”, “Community and Social Services”, “Legal Occupations”, “Education, Training, and Library Occupations”, “Arts, Design, Entertainment, Sports, and Media”, “Healthcare Practitioners and Technical Occupations”.

Applied to Any Blue Collar Job Last Week is an indicator variable equal to one if the respondent applied to a blue collar job within the last seven days and zero otherwise. The variable has been constructed using information from the weekly follow-up surveys which asked “Please list the three most recent jobs you applied to in the last 7 days. If you applied to more than one of the same kind of job, list each job separately. (examples of job titles include: waiter, computer technician, warehouse worker, administrative assistant, etc.)” The answers in the text entry fields were then categorized into Standard Occupational Categories (SOC) by trained staff at the University of Wisconsin Survey Center. 97% of job titles could be successfully matched to 3-digit SOC codes. We code the following 2000 Major Groups as ‘blue collar’: “Building and Grounds Cleaning and Maintenance”, “Farming, Fishing, and Forestry”, “Construction and Extraction Occupations”, “Installation, Maintenance, and Repair Occupations”, “Production”, “Transportation and Material Moving”.

Applied to Any Service Job Last Week is an indicator variable equal to one if the respondent applied to a service job within the last seven days and zero otherwise. The variable has been constructed using information from the weekly follow-up surveys which asked “Please list the three most recent jobs you applied to in the last 7 days. If you applied to more than one of the same kind of job, list each job separately. (examples of job titles include: waiter, computer technician, warehouse worker, administrative assistant, etc.)” The answers in the text entry fields were then categorized into Standard Occupational Categories (SOC) by trained staff at the University of Wisconsin Survey Center. 97% of job titles could be successfully matched to 3-digit SOC codes. We code the following 2000 Major Groups as ‘service jobs’: “Healthcare Support Occupations”, “Protective Service Occupations”, “Food Preparation and Serving Related Occupations”, “Personal Care and Service Occupations”, “Sales and Related Occupations”.

Reservation Wage denotes the lowest hourly wage such that the respondent would accept a job offer. The variable is taken from the weekly follow-up surveys which asked “Suppose someone offered you a job today. What is the lowest wage or salary you would accept (before deductions)

for the type of work you are looking for?” In converting answers referring to yearly, monthly, or weekly time frames into hourly wages we assume 50 work weeks per year and a 40 hour work week.

Bargained over Offer in Hand is an indicator variable equal to one if the respondent bargained with an employer over a job offer she had received. The variable is taken from the weekly follow-up surveys which asked “When you were offered this job, did the employer make a ‘take-it-or leave-it’ offer or was there some bargaining that took place over the pay?” The set of possible answers was: “‘Take-it-or leave-it’ offer”, and “Some bargaining over pay”.

Chose \$20 Now over \$40 in 12 Weeks is an indicator equal to one if the respondent chose to receive a \$20 Visa gift card now, and zero if she opted for a \$40 one to be received in 12 weeks. The exact phrasing of the question was “Thank you for taking the time to complete this week’s survey! [...] To express our thanks, we would like to mail you a Visa gift card. You can choose between the following two options: ○A \$20 Visa gift card that will be mailed to you today. ○A \$40 Visa gift card that will be mailed to you in 12 weeks from today. If you choose the second option, we will send you the Visa gift card even if you don’t return to this survey during the next 12 weeks. Please click here if you would like more information about the Visa gift card.”

Distance Traveled Looking for Work denotes a set of mutually exclusive indicator variables indicating how far the respondent traveled within the last week to look for work. The variable is taken from the weekly follow-up surveys which asked “In the last 7 days, what is the farthest distance that you traveled to look for work?” The set of possible answers was: “Did not go out to look (used internet, mail, or telephone)”, “Less than 5 miles”, “5-10 miles”, “11-25 miles”, “26-50 miles”, “51-100 miles”, “Over 100 miles”.

Metropolitan Area denotes the metropolitan area, as identified in the commercial product *Geolytics Estimates premium 2010*, in which a respondent resides.

B.2 Displaced Workers Survey (DWS)

Sponsored by the Employment and Training Administration of the U.S. Department of Labor, the Displaced Workers Survey (DWS) is a national survey gathering information on the severity of job displacements and to assess employment stability. Since 1994 the DWS has been conducted as a biannual supplement to the Current Population Survey (CPS)—a monthly nationally representative

labor force survey which interviews roughly 56,000 households across the US.⁴³ In 2008 and 2010 the DWS was administered together with the January CPS. Our raw data for the DWS (and the January CPS) have been obtained from the National Bureau of Economic Research's (NBER) website.⁴⁴

To be eligible for the DWS a worker had to be part of the CPS universe, at least 20 years of age, and lost or left a job during the previous three years because her plant or company closed or moved, there was insufficient work for her to do, or their position or shift was abolished. In our analysis we restrict attention to individuals of prime working age, i.e. those who are between 20 and 55 years old, who are (at the time of the survey) neither enrolled in school nor enlisted in the military, and who are neither missing information on their current weekly earnings nor on race. Imposing these restrictions and pooling across the 2008 and 2010 waves leaves us with 5,098 observations. To account for unequal sampling probabilities we use the DWS probability weights provided with the data.

The following describes the variables in our analysis:

Race is a set of mutually exclusive indicator variables, i.e. White, Black, Hispanic, Asian, and Other Race, that denote a respondent's racial identification. In our regressions White serves as the omitted category.

Female is an indicator variable that equals one if the respondent is female and zero otherwise.

Age denotes the respondent's age in years.

Urban is an indicator variable equal to one if the respondent lives in a Metropolitan Statistical Area, and zero otherwise.

Educational Attainment is a set of mutually exclusive indicator variables, i.e. High School Dropout, High School Graduate, Some College, and College Graduate, that denote a respondent's highest level of completed education. In our coding of this variable we combine several categories in the finely distinguished raw data, to arrive at this classification.

⁴³For more information on the CPS and its sampling design see <<http://www.bls.gov/cps/>>.

⁴⁴Currently, the data are available at <http://www.nber.org/data/cps_basic.html>.

Weekly Earnings denotes a respondent’s weekly earnings on her current (main) job. The information for this variable stems from the main part of the CPS as well as the Displaced Workers supplement. We use the edited variables that are released with the data giving preference to the information contained in the main part of the CPS. We discard observations with reported weekly earnings below \$100 or above \$8,000.

Previous Earnings denotes a respondent’s weekly earnings on the job from which she was displaced. The information for this variable stems directly from Displaced Workers Survey. We use the edited variable that is released with the data and discard observations with reported weekly earnings below \$100 or above \$8,000.

Year denotes the year in which the survey was administered, i.e. 2008 or 2010.

State is the FIPS code for a respondent’s state of residence.

Previous Industry corresponds to the “detailed industry recode” with respect to a respondent’s job from she was displaced. The variable is released as part of the DWS.

B.3 National Longitudinal Survey of Youth 1979 (NSLY79)

The National Longitudinal Survey of Youth 1979 (NSLY79) is a nationally representative sample of 12,686 young men and women who were between 14 and 22 years old when they were first interviewed in 1979. These individuals have been surveyed annually through 1994 and biannually thereafter. Covered topics include: family background and demographic characteristics, household composition, marital and fertility histories, labor market experiences, training investments, schooling and aptitude information, military experience, income and assets, health conditions, injuries, and insurance coverage, alcohol and substance use, criminal behavior, attitudes and aspirations, and more.

The NLSY79 consists of three subsamples: (i) A cross-sectional sample of 6,111 individuals designed to be representative of the noninstitutionalized US population ages 14–21 as of December 31, 1978; (ii) a supplemental sample of 5,295 individuals oversampling civilian Hispanics, blacks, and economically disadvantaged non-Hispanic whites living in the US and between the ages of 14–21 as of December 31, 1978; (iii) a military sample of 1,280 individuals designed to be representative of the population between the ages of 17–21 as of December 31, 1978 and enlisted in the active

branches of the military as of September 30, 1978. Our data has been obtained from the NLSY website.⁴⁵ For additional information on the NLSY79 see the NLS Handbook.⁴⁶

B.3.1 Analysis in Table 3B

In Table 3B we rely on data from the 2000 through 2006 waves of the NLSY. We restricted attention to individuals in the civil labor force who change employers between two successive interview rounds and who are not missing information on current hourly wages at their CPS job—for a final sample of 6,047 observations from 4,143 distinct individuals. To account for unequal sampling probabilities we weight each observation by its cross-sectional year specific sampling weight provided with the data.

The following variables are used:

Race is a set of mutually exclusive indicator variables, i.e. White, Black, and Hispanic, that denote a respondent's racial identification. In our regressions White serves as the omitted category.

Female is an indicator variable that equals one if the respondent is female and zero otherwise.

Age denotes the respondent's age in years.

Urban is an indicator variable equal to one if the respondent's current residence is urban, and equal to zero if it is rural.

Years of Schooling denotes the respondent's highest grade or year of regular school that she has completed and gotten credit for. The variable is top-coded at 20 years of schooling, i.e. eight years or more of tertiary education.

AFQT denotes an individual's standardized score on the Armed Forces Qualification Test. We standardize test scores (to have mean zero and a standard deviation of one) by age at the time the test was taken.

⁴⁵Currently, the NLSY website is located at <http://www.nlsinfo.org>.

⁴⁶The NLS Handbook 2005 is available online at <http://www.bls.gov/nls/handbook/nlshndbk.htm>.

Current Hourly Wage gives a respondent’s hourly wage at the main job she holds at the time of the survey, i.e. the CPS job. The variable is taken from the work history file. We discard observations with reported hourly wages below \$5 and above \$100.

Previous Wage denotes the a respondent’s hourly wage at the main job she held at the time of the previous survey. The variable is taken from the work history file. We discard observations with reported hourly wages below \$5 and above \$100.

Year denotes the year in which the survey was administered, i.e. 2000, 2004, or 2006.

Previous Industry is a set of twelve indicator variables (based on 3-digit 1970 Census classifications) denoting the industry of a respondent’s previous employer, i.e. the employer at the time of the last survey.

B.3.2 Analysis in Table 11

Our analysis in Table 11 closely follows the coding and sample construction procedures in Altonji and Pierret (2001) in order to replicate their results as closely as possible—before extending them. In what follows we lean heavily on the description in Altonji and Pierret (2001, pp. 345). For a more detailed account the interested reader should consult their data appendix directly.

The sample is limited to black and non-Hispanics white males, who left school before 1992; and only jobs after a person has left school are being considered. The time a person leaves school is defined as the “month and year of the most recent enrollment at the first interview where the respondent is not currently enrolled in school” (p. 345). We use Altonji and Pierret’s (2001) exact coding of this variable. Further sample restrictions include: at least eight years of education, at least one valid observation on wages, no missing data on AFQT score, no missing information on first occupation, and no missing information other variables.⁴⁷ Altonji and Pierret’s (2001) final sample contains 2,976 individuals. To rule out that sample selection drives our results, we use this *exact* set of individuals in our analysis.

Employment is only considered for the current (or most recent) CPS employer, and only if the respondent is working at the job in the week of the interview. In case of two concurrent jobs, only the job at which the respondent works the most hours is considered—regardless of whether it is

⁴⁷Altonji and Pierret (2001) also drop 805 respondents who left school before 1978 for whom they could not reconstruct their work history.

full- or part-time. Military jobs, however, are excluded. All valid observations are included, even if individuals did not participate in particular waves of the NLSY. Moreover, Altonji and Pierret (2001) use all subsamples of the NLSY, and focus waves 1979-92. So do we. Our replication sample consists of 21,026 observations—compared to 21,058 in their Table 1.⁴⁸ In columns (7) and (8) of Table 11 we add data for the 1993–2006 waves of the NLSY, using the sample restrictions outlined above. This extends the sample to 33,931 observations.

The following describes the coding of the variables used throughout the analysis:

Race is a set of mutually exclusive indicator variables, i.e. White, and Black, that denote a respondent’s racial identification. In our regressions White serves as the omitted category.

Years of Schooling denotes the respondent’s highest grade or year of regular school that she has completed and gotten credit for. The variable is top-coded at 20 years of schooling, i.e. eight years or more of tertiary education.

AFQT denotes an individual’s standardized score on the Armed Forces Qualification Test. We standardize test scores (to have mean zero and a standard deviation of one) by age at the time the test were taken.

Potential Experience is coded as a respondent’s current age minus her years of schooling minus six.

Hourly Wage denotes a respondent’s real hourly wage at her CPS job. The raw variable is taken from the work history file. To convert nominal into real wages we use the Personal Consumption Expenditures: Chain-type Price Index (PCECTPI) constructed by the U.S. Department of Commerce: Bureau of Economic Analysis, and set 1987 as the base year. Following Altonji and Pierret (2001) we discard wage observations with real hourly wages below \$2 and in excess of \$100.

Tenure denotes a respondent’s total tenure (in years) with the employer at her CPS job.

Urban Residence is an indicator variable equal to one if the respondent’s residence at the time of the survey is urban, and equal to zero if it is rural.

⁴⁸For 32 observations included in the sample of Altonji and Pierret (2001) the work history file of the NLSY79 did not contain a valid wage. We suspect this may be due to later revisions and consistency checks applied to the raw data.

Occupation at First Job denotes the two-digit occupation at the respondent's first job after leaving school. We obtain this variable directly from Altonji and Pierret (2001).

Year denotes the year in which the survey was administered. The NSLY79 surveyed participants on a yearly basis from 1979–94 and every other year thereafter.

C Additional Results

See Tables C.1–C.7.

Figure 1: Bellman's Functional Equation

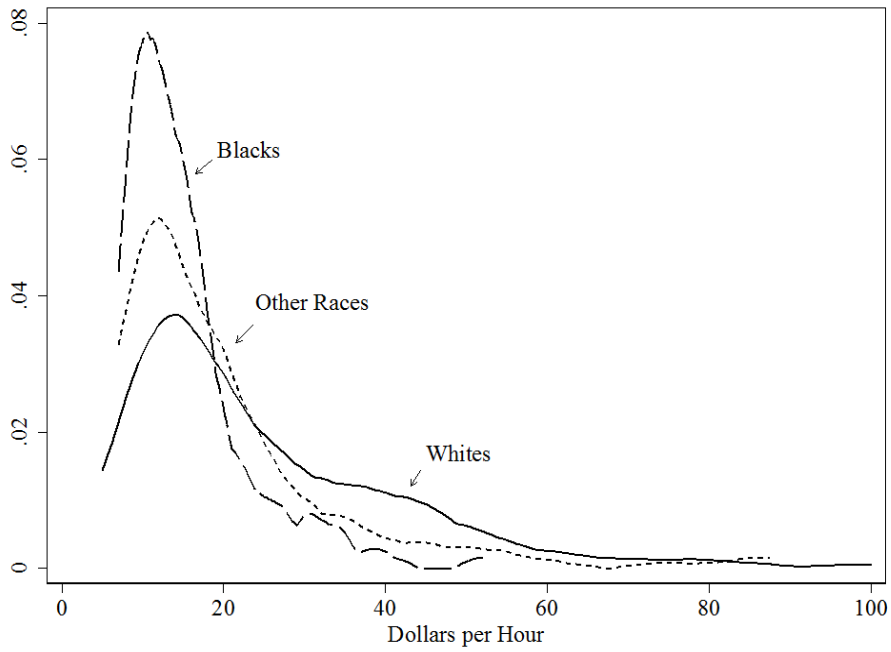

Figure 2: Distribution of Wage Offers, by Race

Notes: Figure displays kernel density estimates of the distribution of wage offers in the raw NJ UI data, separately by race. 'Whites' refers to non-Hispanic whites, 'Blacks' to non-Hispanic blacks, and 'Other Races' is the residual category.

Table 1: Summary Statistics, NJ UI Data

Variable	Full Sample	White	Black	Other Races
Demographics:				
Female	.471 (.499)	.445 (.497)	.579 (.494)	.439 (.597)
Age	41.6 (13.5)	44.7 (13.6)	37.6 (12.3)	38.2 (12.6)
Educational Attainment:				
High School Dropout	.072 (.258)	.039 (.193)	.109 (.311)	.112 (.316)
High School Graduate	.301 (.459)	.293 (.455)	.360 (.480)	.269 (.443)
Some College	.352 (.478)	.349 (.477)	.362 (.481)	.349 (.477)
College Graduate	.275 (.447)	.319 (.466)	.169 (.375)	.270 (.444)
Weeks Unemployed at Beginning of Survey	42.9 (30.9)	42.2 (30.2)	46.6 (34.2)	41.4 (29.4)
Previous Job:				
Weekly Earnings	857 (688)	992 (767)	603 (438)	779 (604)
Years of Tenure	4.69 (6.46)	5.32 (6.84)	3.47 (5.49)	4.35 (6.19)
Last Job was Temporary	.157 (.364)	.140 (.347)	.190 (.393)	.164 (.370)
Quit Last Job	.045 (.208)	.039 (.194)	.062 (.241)	.044 (.204)
Laid Off from Last Job	.798 (.401)	.820 (.384)	.747 (.435)	.793 (.406)

Notes: Entries in columns (1)-(4) are coefficients and standard errors from replicating the upper panel of Table 1 in Altonji and Pierret (2001). Columns (5)-(9) extend their analysis by controlling for tenure and adding additional years of data. As in Altonji and Pierret (2001) the sample consists of black and white non-Hispanic males, and the base year of the time trends is the last year of period under consideration. Heteroskedasticity robust standard errors are clustered by individual and reported in parentheses. See the Data Appendix as well as Altonji and Pierret (2001) for a description of the sample construction procedures.

Table C.1: Robustness and Sensitivity Analysis

	OLS	OLS	OLS	OLS	Matching Estimator	OLS	OLS
	Baseline	Square in Log Previous Earnings	Only Best Offer	Only Accepted Offers	(Using Best Offers)	Oaxaca Decomposition	Difference between Offered and Previous Wage
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Black	-.160 (.060)	-.154 (.057)	-.140 (.062)	-.107 (.068)	-.227 (.031)	-.140 (.100)	-.111 (.092)

Controls							
Demographics, Education	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Duration of Unemployment, Quit Last J	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Previous Industry, Previous Wage	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Notes: Entries are coefficients and standard errors on racial indicators from estimating the empirical model by weighted least squares. Standard errors are clustered by individual (if applicable) and reported in parentheses. In addition to the controls shown in the table, indicator variables for missing values on each covariate are also included in the regressions. See the Data Appendix for the precise definition and source of each variable. Column (1) shows our main result from Table 2, and column (2) adds the square of Log Previous Weekly Earnings to the set of controls. Estimates of our baseline specification using only individuals' best offers during the 12 week survey period are displayed in column (3). Similarly, column (4) uses only accepted offers. Results using the nearest neighbor matching estimator in Imbens and Abadie (2002) are shown in column (5). Column (6) performs an Oaxaca decomposition of racial difference in offered wages. The displayed estimates correspond to the racial gap due to differences in coefficients (using the parameters estimated for whites as reference). To account for measurement error or mean reversion in previous wages column (7) estimates racial gaps in the difference between an offered hourly wage and an individual's hourly wage on the previous job. Note that this is equivalent to estimating our

Table C.2: Racial Differences in Wage Offers, NJ UI Data — Males

Notes: Entries are coefficients and standard errors from estimating the empirical model by weighted least squares. Heteroskedasticity robust standard errors are clustered by individual and reported in parentheses. In addition to the variables shown in the table, indicator variables for missing values on each covariate are also included in the regressions. See the Data Appendix for the precise definition and source of each

Table C.4: Racial Differences in Wage Offers in 3 Major Industries, NJ UI Data

Independent Variable	Log Offered Hourly Wage			
	(1)	(2)	(3)	(4)
Black	-.160 (.060)	-.229 (.088)	-.085 (.101)	-.338 (.107)
Other Races	-.201 (.063)	-.044 (.132)	-.167 (.118)	-.238 (.127)
Female	-.114 (.048)	.079 (.105)	-.126 (.094)	-.057 (.084)
Age	.002 (.014)	-.016 (.021)	.012 (.016)	.002 (.012)
Age Squared ($\div 100$)	.001 (.017)	.031 (.025)	-.012 (.016)	-.004 (.013)
High School Graduate	-.086 (.099)	-.471 (.101)	-.119 (.173)	.130 (.147)
Some College	.084 (.094)	-.435 (.121)	.013 (.139)	.276 (.144)
College Graduate	.206 (.098)	-.177 (.104)	.229 (.134)	.309 (.173)
<i>Log Previous Weekly Earnings</i>	.417 (.051)	.379 (.088)	.390 (.090)	.346 (.056)
Weeks Unemployed	-.006 (.003)	-.008 (.003)	-.000 (.004)	.001 (.003)
Weeks Unemployed Squared ($\div 100$)	.003 (.002)	.003 (.002)	-.000 (.002)	-.001 (.002)
Quit Last Job	-.006 (.105)	.463 (.151)	.091 (.159)	-.383 (.159)
Last Job was Temporary	.044 (.069)	.111 (.118)	.160 (.106)	.043 (.147)
Constant	.146 (.390)	.962 (.721)	-.042 (.625)	.285 (.360)
Industry	All	Educational and Health Care Services	Professional, Scientific and Technical Services	Wholesale and Retail Trade
R-Squared	.512	.724	.479	.483
Number of Observations	1,194	184	411	240

Notes: Entries are coefficients and standard errors from estimating the empirical model by weighted least squares for the three industries with more than 100 observations in the NJ UI data. Heteroskedasticity robust standard errors are clustered by individual and reported in parentheses. In addition to the variables shown in the table, indicator variables for missing values on each covariate are also included in the regressions. See the Data Appendix for the precise definition and source of each variable.

Table C.5: Residual Racial Differences in Wage Offers — Males

	Log Offered Hourly Wage						
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Black	-.132	-.107	-.167	-.138	-.139	-.112	-.185
	(.115)	(.105)	(.119)	(.117)	(.117)	(.103)	(.097)
Other Races	-.192	-.186	-.150	-.184	-.188	-.254	-.164
	(.094)	(.087)	(.079)	(.095)	(.094)	(.109)	(.070)
Controls							
Demographics, Education	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Duration of Unemployment, Quit Last Job	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Previous Industry, Previous Wage	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Search Intensity	No	Yes	No	No	No	No	Yes
Search Strategy	No	No	Yes	No	No	No	Yes
Bargaining	No	No	No	Yes	No	No	Yes
Discounting	No	No	No	No	Yes	No	Yes
County Fixed Effects	No	No	No	No	No	Yes	Yes

Notes: Entries are coefficients and standard errors from estimating the empirical model by weighted least squares. Heteroskedasticity robust standard errors are clustered by individual and reported in parentheses. See the Data Appendix for the precise definition and source of all variables.

Table C.6: Residual Racial Differences in Wage Offers — Females

	Log Offered Hourly Wage						
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Black	-.219 (.062)	-.189 (.063)	-.219 (.053)	-.203 (.059)	-.218 (.063)	-.155 (.061)	-.130 (.052)
Other Races	-.189 (.073)	-.161 (.072)	-.197 (.049)	-.192 (.071)	-.189 (.074)	-.176 (.065)	-.162 (.055)
Controls							
Demographics, Education	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Duration of Unemployment, Quit Last Job	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Previous Industry, Previous Wage	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Search Intensity	No	Yes	No	No	No	No	Yes
Search Strategy	No	No	Yes	No	No	No	Yes
Bargaining	No	No	No	Yes	No	No	Yes
Discounting	No	No	No	No	Yes	No	Yes
County Fixed Effects	No	No	No	No	No	Yes	Yes

Notes: Entries are coefficients and standard errors from estimating the empirical model by weighted least squares. Heteroskedasticity robust standard errors are clustered by individual and reported in parentheses. See the Data Appendix for the precise definition and source of all variables.

Table C.7: Racial Differences in Wages and the Return to Tenure, NJ UI Data — Males

Independent Variable	Log Weekly Earnings on Previous Job		
	(1)	(2)	(3)
Black	-.382 (.050)	-.258 (.047)	-.305 (.054)
Other Races	-.194 (.054)	-.152 (.047)	-.191 (.056)
Age	.094 (.008)	.079 (.007)	.075 (.007)
Age Squared ($\div 100$)	-.091 (.009)	-.080 (.008)	-.077 (.008)
High School Graduate		.076 (.075)	.070 (.074)
Some College		.288 (.077)	.286 (.075)
College Graduate		.643 (.075)	.649 (.074)
Weeks Unemployed		-.001 (.002)	-.000 (.002)
Weeks Unemployed Squared ($\div 100$)		-.000 (.001)	-.001 (.001)
Quit Last Job		.085 (.082)	.111 (.078)
Last Job was Temporary		-.086 (.049)	-.047 (.049)
<i>Tenure on Previous Job</i>			.019 (.003)
<i>Tenure on Previous Job \times Black</i>			.010 (.006)
<i>Tenure on Previous Job \times Other Races</i>			.008 (.006)
Constant	4.581 (.164)	4.703 (.177)	4.726 (.168)
Previous Industry Fixed Effects	No	Yes	Yes
R-Squared	.218	.386	.433
Number of Observations	2,487	2,487	2,487

Notes: Entries are coefficients and standard errors from estimating the empirical model by weighted least squares. Heteroskedasticity robust standard errors are reported in parentheses. In addition to the variables shown in the table, indicator variables for missing values on each covariate are also included in the regressions. See the Data Appendix for the precise definition and source of each variable.

Table C.8: Racial Differences in Wages and the Return to Tenure, NJ UI Data — Females

Independent Variable	Log Weekly Earnings on Previous Job		
	(1)	(2)	(3)
Black	-.261 (.040)	-.167 (.034)	-.194 (.037)
Other Races	-.080 (.041)	-.074 (.039)	-.045 (.047)
Age	.050 (.007)	.039 (.006)	.036 (.006)
Age Squared ($\div 100$)	-.045 (.008)	-.034 (.008)	-.034 (.007)
High School Graduate		.190 (.055)	.172 (.052)
Some College		.326 (.051)	.320 (.049)
College Graduate		.633 (.052)	.635 (.050)
Weeks Unemployed		.000 (.001)	.001 (.001)
Weeks Unemployed Squared ($\div 100$)		-.000 (.001)	-.001 (.001)
Quit Last Job		-.113 (.053)	-.085 (.054)
Last Job was Temporary		-.232 (.042)	-.185 (.043)
<i>Tenure on Previous Job</i>			.018 (.003)
<i>Tenure on Previous Job \times Black</i>			.012 (.005)
<i>Tenure on Previous Job \times Other Races</i>			-.009 (.008)
Constant	5.260 (.133)	5.167 (.143)	5.195 (.135)
Previous Industry Fixed Effects	No	Yes	Yes
R-Squared	.133	.336	.366
Number of Observations	2,720	2,720	2,720

Notes: Entries are coefficients and standard errors from estimating the empirical model by weighted least squares. Heteroskedasticity robust standard errors are reported in parentheses. In addition to the variables shown in the table, indicator variables for missing values on each covariate are also included in the regressions. See the Data Appendix for the precise definition and source of each variable.

Table C.9: Racial Differences in Wages and the Return to Tenure, NJ UI Data — Various Samples

Independent Variable	Log Weekly Earnings on Previous Job			
	(1)	(2)	(3)	(4)
Black	-.252 (.032)	-.335 (.062)	-.232 (.039)	-.423 (.128)
Other Races	-.123 (.039)	-.138 (.071)	-.096 (.048)	.004 (.131)
Female	-.210 (.022)	-.260 (.033)	-.201 (.024)	-.255 (.040)
Age	.054 (.005)	.053 (.009)	.052 (.006)	.053 (.012)
Age Squared ($\div 100$)	-.054 (.006)	-.053 (.009)	-.051 (.006)	-.053 (.013)
High School Graduate	.130 (.047)	.112 (.075)	.113 (.051)	.060 (.096)
Some College	.316 (.047)	.320 (.074)	.291 (.050)	.254 (.091)
College Graduate	.655 (.047)	.604 (.074)	.636 (.051)	.545 (.092)
Weeks Unemployed	-.000 (.001)	.000 (.001)	-.001 (.001)	-.001 (.002)
Weeks Unemployed Squared ($\div 100$)	-.001 (.001)	-.000 (.001)	-.000 (.001)	-.000 (.001)
Quit Last Job	.006 (.049)	-.080 (.070)	.040 (.051)	-.016 (.078)
Last Job was Temporary	-.110 (.033)	-.273 (.068)	-.081 (.034)	-.262 (.084)
<i>Tenure on Previous Job</i>	.019 (.002)	.013 (.002)	.034 (.007)	.024 (.012)
<i>Tenure on Previous Job</i> \times <i>Black</i>	.011 (.004)	.017 (.005)	.013 (.012)	.044 (.025)
<i>Tenure on Previous Job</i> \times <i>Other Races</i>	.000 (.005)	.001 (.007)	-.011 (.013)	-.031 (.023)
Constant	5.096 (.115)	5.265 (.226)	5.118 (.126)	5.254 (.285)
Previous Industry Fixed Effects	Yes	Yes	Yes	Yes
Sample Restriction	None	> 2 Years of Tenure	< 10 Years of Tenure	> 2 and < 10 Years of Tenure
R-Squared	.415	.381	.383	.327
Number of Observations	5,207	2,694	4,284	1,771

Notes: Entries are coefficients and standard errors from estimating the empirical model in Table 10 by weighted least squares on different subsamples of the data. Heteroskedasticity robust standard errors are reported in parentheses. In addition to the variables shown in the table, indicator variables for missing values on each covariate are also included in the regressions. See the Data Appendix for the precise definition and source of each variable.
