Expanding “Choice” in School Choice

ATILA ABDULKADIROĞLU, YEON-KOO CHE, AND YOSUKE YASUDA*

September 24, 2008

Abstract: Truthful revelation of preferences has emerged as a desideratum in the design of school choice programs. Gale-Shapley’s deferred acceptance mechanism is strategy-proof for students but limits their ability to communicate their preference intensities. This results in ex-ante inefficiency when ties at school preferences are broken randomly. We propose a variant of deferred acceptance mechanism which allows students to influence how they are treated in ties. It maintains truthful revelation of ordinal preferences and supports a greater scope of efficiency.

Keywords: Gale-Shapley’s deferred acceptance algorithm, choice-augmented deferred acceptance, tie breaking, ex ante Pareto efficiency.

1 Introduction

Public school choice has been a subject of intense research and policy debate in recent years. The idea of expanding one’s choice of school beyond his/her residence area has broad public support, as exemplified by the number of districts that offer parental choice

We are grateful to Francis Bloch, Peter Coles, Olivier Compte, Matt Jackson, Philippe Jehiel, Navin Kartik, Fuhito Kojima, Paul Milgrom, Andrew Postlewaite, Al Roth, Ilya Segal and other seminar participants at Caltech, Duke University, GREQAM, Harvard Market Design Workshop, Hong Kong University, Paris School of Economics, Institute for Advanced Studies at Princeton, Stanford University, University of Pompeu Fabra, and Yonsei University.
over public schools. Yet, how to operationalize the idea of school choice remains actively debated.

This debate, initiated by Abdulkadiroğlu and Sönmez (2003), is centered around a popular method, the “Boston” mechanism, which was used by Boston Public Schools (BPS) until the 2004-2005 school year to assign K-12 pupils to the city schools. Under the Boston mechanism, each school assigns its seats in the order students rank that school during registration. Specifically, each school accepts first those who rank it the first, and accepts those who rank it the second, only when the seats are available, and so forth. Under this system, a student’s ranking of a school matters crucially for her chance of assignment at that school. This feature may engender strategic behavior in the families’ application. For instance, a family may not list their most preferred school as the top choice if that school is very popular among others: Ranking it at the top will not improve their chance with that school appreciably, but it may rather jeopardize their shot at their second, or even less, preferred school, which could have been available to them if they had ranked it at the top instead. This incentive to “game the system” raises difficulties for families and administrators alike.

In 2005, BPS replaced the Boston mechanism with the student-proposing deferred acceptance (henceforth DA) mechanism. Originally proposed by David E. Gale and Lloyd S. Shapley (1962), the DA has students apply to schools in the order they rank them, but schools select the students based solely on their priorities with each school. Specifically, in the first round students apply to their top-ranked schools, and the schools select from them according to their priorities, up to their capacities but only tentatively, and reject the others. In the second round, those rejected by their top choice apply to their second-ranked schools, and schools reselect from those held from the first round and from new applicants up to their capacities (only based on the school’s ranking of them), again tentatively, and reject the others. This process continues until no students are rejected, at which point the tentative assignment becomes final. A crucial difference relative to the Boston is that a student’s ranking of a school does not affect her chance of assignment at that school, once he/she applies to that school in the process. This means that the families have dominant strategies to report truthfully about their rankings, a property known as “strategyproof-

---

1 Government policies that allow parents to choose schools for their children take various forms, including interdistrict and intradistrict public school choice, offered widely across the US, as well as open enrollment, tax credits and deductions, education savings accounts, publicly funded vouchers and scholarships, private voucher programs, contracting with private schools, home schooling, magnet schools, charter schools and dual enrollment. See an interactive map at http://www.heritage.org/research/Education/SchoolChoice/SchoolChoice.cfm for a comprehensive list of choice plans throughout the US.

2 It also raises a fairness issue since not all families may be equally sophisticated at strategizing. Cite..
ness” (Dubins and Freedman, 1981; Roth, 1982). For instance, top-ranking a very popular school will not jeopardize one’s chance at less preferred schools in case he/she fails to get into the top school.

Besides strategyproofness, the DA mechanism is well-justified in terms of student welfare, if student and school preferences do not involve indifferences. Given strict preferences on both sides, the DA algorithm produces the so-called student optimal stable matching — a matching that is most preferred by every student among all stable matchings (Gale and Shapley, 1962).\(^3\) By contrast, any stable matching may arise in a full-information Nash equilibrium of the Boston mechanism (Ergin and Sönmez, 2006).

In practice, however, schools do not have strict preferences over students. For instance, the Boston public schools prioritize applicants based on whether students have siblings attending a given school or whether they live within its walk zone. This leaves many students in the same priority class. Authors have recognized that no mechanism the a

The resulting indifferences in school preferences present challenges in attaining the dual objectives of strategyproofness and welfare, for no strategy-proof mechanism implements a student-optimal stable matching for every preference profile (Erdil and Ergin, forthcoming).

Furthermore, one has to break ties at school preferences in order to adopt the DA mechanism, and any inefficiency associated with a realized tie-breaking can not be removed ex post without harming students’ incentives ex ante (Abdulkadiroğlu, Pathak and Roth, 2006).\(^4\)

that simplifies parents’ strategic choices by making it safe for them to state their true preference lists. Although many parents recognized the possibility of strategic manipulation of preferences under the Boston mechanism, some parents did see it as a merit, not as a shortcoming of the mechanism. Indeed, at a public hearing by the BPS School Committee, a parent argued:

I’m troubled that you’re considering a system that takes away the little power that parents have to prioritize... what you call this strategizing as if strategizing is a dirty word...\(^5\)

As we will demonstrate, this sentiment reflects a legitimate welfare consideration.

Yet, these negative conclusions, and the rest of the literature on school choice, are concerned with students’ ex post ordinal welfare, namely, how well a given procedure assigns students based on their preference orderings for a realized tie-breaking. This perspective

\(^3\)A matching is stable if no student or school can do strictly better by breaking off current matching either unilaterally or by rematching with some other partner without making it worse off

\(^4\)Also see Ehlers (2006) on matching with indifferences.

\(^5\)Recording from Public Hearing by the School Committee, 05-11-04
does not capture students’ *ex ante welfare*, i.e., how well a procedure does on average across all realizations of tie-breaking, not just under some realization, and how efficiently it resolves students’ conflicting interests based on their preference intensities, or their *cardinal utilities*.

To illustrate why ex ante welfare matters, suppose there are three students, \{1, 2, 3\}, to be assigned to three schools, \{s_1, s_2, s_3\}, each with one seat. All students are ranked into the same priority class at every school, and students’ preferences are represented by the following von-Neumann Morgenstern (henceforth, vNM) utility values, where \(v_i^j\) is student \(i\)’s vNM utility value for school \(s_j\):

<table>
<thead>
<tr>
<th>(j)</th>
<th>(v_1^j)</th>
<th>(v_2^j)</th>
<th>(v_3^j)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>4</td>
<td>4</td>
<td>3</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>3</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

Every feasible matching that assigns each student to a school is stable due to the indifferences at school preferences. Since the students have the same ordinal preferences, any such assignment is also ex post Pareto efficient, hence student-optimal stable. Therefore, there is no basis for comparing different procedures based on the ex post welfare criterion. In particular, the *stable improvement cycles* algorithm (Erdil and Ergin, forthcoming), which finds a student-optimal stable matching for every preference profile, has no bite in this example. Yet, how the students’ conflicting interests are resolved matters greatly for their ex ante welfare.

To see this, suppose that the ties at school preferences are broken as follows: Assign each student a lottery number uniformly randomly. Whenever two students tie at a school, break the tie in favor of the student with the better lottery number. Then the DA algorithm works as follows in this example: At the first step, each student applies to her most preferred school, which is \(s_1\). The student with the best lottery number is *tentatively* assigned to \(s_1\), and the remaining two applicants are rejected by \(s_1\). Those who are rejected apply to their next most preferred school, which is \(s_2\). Then the student with the better lottery number is *tentatively* assigned to \(s_2\), and the other one is rejected, who then applies to her next choice, \(s_3\), which admits her *tentatively*. There are no more rejections and the DA finalizes all the *tentative* assignments. Since the DA mechanism is strategy-proof, all three submit true ordinal preferences so that they are assigned to the schools with equal probabilities. Hence, the students obtain expected utilities of \(EU_1 = EU_2 = EU_3 = \frac{5}{3}\).

It is easy to see that this assignment is ex ante Pareto-dominated by the following assignment: *Assign student 3 to \(s_2\), and students 1 and 2 randomly between \(s_1\) and \(s_3\),* which yields expected utilities of \(EU'_1 = EU'_2 = EU'_3 = 2 > \frac{5}{3}\). Intuitively, starting from
the random assignment, this latter assignment executes a trading of probability shares of schools by transferring student 3’ share of schools 1 and 3 to students 1 and 2 in exchange of the latter students’ shares of school 2. Such a trade is beneficial for all parties given their preference intensities.

The Boston mechanism works like the DA mechanism with the exception that assignments at every step are final under the Boston mechanism. Therefore, when students 1 and 2 submit their true preference rankings to the Boston mechanism, student 3 can secure $s_2$ by strategically ranking it as her first choice. In that case, students 1 and 2 apply to $s_1$ and student 3 applies to $s_2$ at the first step of the mechanism. Then student 3 gets assigned to $s_2$, whereas one of 1 and 2 is rejected by $s_1$. That student then applies to $s_2$. However, she is rejected by $s_2$ since 1’s assignment at $s_2$ is final. This produces the more efficient matching above. Interestingly, this is the unique Nash equilibrium outcome of the Boston mechanism. The feature of the Boston mechanism crucial for this outcome is that a student can increase his probability of getting a school simply by ranking that school higher in his choice list. This ability to influence one’s treatment in a competition is suppressed in the DA, for a school never discriminates its applicants based on where they rank that school in their choice lists. However, it is this latter property — nondiscrimination of applicants based on choice rankings — that yields the incentives for truthful revelation of preferences in DA. This suggests a tradeoff between incentives and ex ante efficiency. Clearly, the DA is extreme in resolving this tradeoff; it guarantees truthful revelation of preferences but denies students any “say” over how they should be treated by each school. Surprisingly, some parents seem to have found this feature of DA as troublesome, as one parent put it as follows at a BPS Public Hearing:

... if I understand the impact of Gale Shapley, and I’ve tried to study it and I’ve met with BPS staff... And in trying to understand this ... I thought I understood that in fact the random number in fact [has] preference over your choices...7

The current paper suggests that there is a potentially better way to balance the tradeoff. Appreciable welfare gain can be obtained by offering students simple and practical ways to signal their preferences, with no sacrifice of strategy-proofness. We propose a practical procedure that accomplishes this goal and a new efficiency notion that enhances our understanding and ability to compare various assignment mechanisms on the efficiency ground. The next section illustrates our proposal.

---

6This does not contradict Ergin and Sönmez (2006)’s finding that the Boston mechanism is (weakly) Pareto dominated by the DA, which relies on strict preferences by the schools.

7Recording from the BPS Public Hearing, 6-8-05
2 Choice-Augmented DA Algorithm: Illustration

Suppose the students have strict preferences over schools, and the schools have priorities characterized by strict preferences over students. The (student-proposing) DA algorithm is then described as follows: At the first step, each student applies to her most preferred school. Every school tentatively admits its applicants in the order of its priority order of the students. When all of its seats are assigned, it rejects the remaining applicants. In general, each student who was rejected in the previous step applies to her next preferred school. Each school considers the set of students it has tentatively admitted and the new applicants. It tentatively admits from these students in the order of priority. When all of its seats are assigned, it rejects the remaining applicants. The process terminates when no student proposal is rejected.

Suppose now schools’ priorities are characterized by weak preferences. Then, ties must be broken to generate strict school preferences for the DA algorithm to be employed. There are two common methods of tie-breaking. Single tie-breaking randomly assigns every student a single lottery number to break ties at every school, whereas multiple tie-breaking randomly assigns a distinct lottery number to each student at every school. Clearly, a DA algorithm is well defined with respect to the strict priority list generated by either method. We refer the DA algorithms using single and multiple tie-breaking by DA-STB and DA-MTB, respectively.

We propose an alternative way to break a tie, one that allows students to influence its outcome based on their communication. The associated DA algorithm, which we refer as Choice-Augmented Deferred Acceptance (henceforth, CADA), is described as follows:

- **Step 1:** All students submit ordinal preferences, plus an “auxiliary message,” naming one’s “target” school.

- **Step 2:** The schools’ strict priorities over students are generated based on their inherent priorities and the students’ auxiliary messages, as follows. First, each student is independently randomly assigned two lottery numbers. Call one target lottery number and the other regular lottery number. Each school’s strict priority list is then generated as follows: (i) First consider the students in the school’s highest priority group. Within that group, rank at the top those who name the school as their target. List them in the order of their target lottery numbers, and list below them the rest (who didn’t name that school for target) according to their regular lottery numbers. (ii) Move to the next highest priority group, and list them below in the same fashion, and repeat this process until all students are ranked in a strict order.

- **Step 3:** The students are then assigned to schools via the DA algorithm, using
each student’s ordinal preferences from Step 1 and each school’s strict priority list compiled in Step 2.

To illustrate Step 2, suppose there are five students $N = \{1, 2, 3, 4, 5\}$ and two schools $S = \{A, B\}$, neither of which has inherent priority ordering over the students. Suppose students 1, 3 and 4 named $A$ for target and 2 and 5 named $B$ for target, and that students are ordered according to their target and regular lottery numbers as follows:

$$T(N) : 3 - 5 - 2 - 1 - 4; \quad R(N) : 3 - 4 - 1 - 2 - 5.$$  

Then the priority list for school $A$ first reorders students $\{1, 3, 4\}$, who named that school as target, based on $T(N)$, to $3 - 1 - 4$, and reorders the rest, $\{2, 5\}$, based on $R(N)$ to $2 - 5$, which produces a complete list for $A$:

$$P_A(N) = 3 - 1 - 4 - 2 - 5.$$  

The priority list for $B$ is determined as

$$P_B(N) = 5 - 2 - 3 - 4 - 1.$$  

The process of compiling the priority lists resembles the STB in that the same lottery is used by different schools, but only within each group. Unlike STB, though, different lotteries are used across different groups. This ensures that a student who has a bad draw at her target school gets a “new lease of life” with another independent draw for the other schools.\(^8\)

Clearly, the deferred acceptance feature preserves stability and the incentives to reveal the ordinal preferences truthfully; the gaming aspect is limited to manipulating the outcome of tie-breaking. This limited introduction of “choice signaling” can however improve upon the DA rule in a significant way. In the above example, the CADA implements the Pareto superior matching: All students will submit the ordinal preferences truthfully, but 1 and 2 will choose $s_1$ as their target, and 2 will choose $s_2$ as her target. In this case, the CADA resembles the Boston mechanism.

In general, CADA is different from the Boston mechanism. In fact, if schools have many priorities (so their preferences are almost “strict”), then the auxiliary message would have little bite; thus the CADA will very much resemble the DA. Furthermore, CADA delivers a more efficient matching without sacrificing strategy-proofness. The rest of the paper makes

\(^8\)Although the primary reason for our choice is technical, this choice also has additional benefit of allaying a similar concern about the STB raised in the wake of the NYC redesign. One criticism against STB was that if a student has a bad draw, then she will not have a low priority with just one or two schools, but with every school she applies to. CADA mitigates this problem
this sense precise. That is, we demonstrate the nature of welfare benefits that CADA will have relative to the DA algorithms, when there are sufficiently numerous students and numerous school seats.

Specifically, we consider a model of a “large” economy populated by a continuum of students and a finite number of schools each with a continuum of capacities. We then compare alternative procedures, DA-STB, DA-MTB and CADA, in terms of the scope of efficiency achieved under different procedures. To illustrate our approach, suppose a procedure determines for each student the probabilities of her getting assigned to alternative schools. Call these her shares of schools. Then the “scope of efficiency” can be measured by the set of schools whose shares cannot be traded among students in a way that benefits all the students. The bigger this set is, arguably the more efficient the outcome is, with the outcome being fully Pareto efficient if the set coincides with the entire set of schools.

Our main result is then stated in this term: The CADA mechanism supports a greater scope of efficiency than the DA mechanisms with either tie-breaking procedure. Specifically, the DA mechanisms supports efficient allocation of at most a pair of schools, whereas CADA supports efficient allocation of a (weakly) bigger set of schools. In particular, CADA entails efficient allocation among schools that are relatively popular—in the sense of being oversubscribed by students in their target choice. The economics of this property closely resembles that of competitive markets. Essentially, the students participating in CADA can be seen as making purchasing decisions on the shares of schools. For instance, a student can raise her share of a school, say A, by naming it for her target, but that lowers her priority standing in other schools, say B and C, thus reducing her shares of those schools. The exact tradeoffs faced by a student are determined by how many other students are picking A, rather than B or C, for their targets. If there are many such students, then raising a share of A is “expensive,” for it requires giving up large amounts of shares of B and C. In other words, relative degrees of congestion at different schools act as “prices” that regulate individuals’ decisions. In a “large” economy, students become price takers, so the resulting allocation resembles that of competitive markets, which, as is well known, yields an efficient allocation (among the oversubscribed schools).

In addition to showing the benefit of CADA, we also argue that DA-STB is more desirable than DA-MTB from an ex ante welfare perspective. In particular, we show that the former supports greater scope of efficiency than the latter. The choice between single versus multiple tie-breaking has proven to be an important policy choice in high school admissions in New York City. Our finding informs the choice between DA-STB and DA-MTB in favor of the former.

The idea of CADA appears similar to the proposal by Sönmez and Ünver (2003) to

---

9See Abdulkadiroğlu, Pathak and Roth (2008) for a detailed discussion.
imbed the DA algorithm in “course bidding” employed by some business schools. These two proposals differ in the application, however, as well as in the nature of the inquiry: We are interested in studying the benefit of adding a “signalling” element to the DA algorithm. By contrast, their interest is in studying the effect of adding ordinal preferences and the DA feature to the course bidding. In a broader sense, our paper is an exercise of mechanism design without monetary transfers, and in fact it is closer in nature to the recent ideas of “storable votes” (see Casella (2005)) and “linking decisions” (see Jackson and Sonnenschein, forthcoming). Just like them, CADA “links” how a student is treated in a tie at one school to how she is treated in a tie at another school, and this linking makes communication credible. Clearly, applying the idea in a centralized matching is novel and differentiates the current paper. There is a further difference. Jackson and Sonnenschein (forthcoming) demonstrated the efficiency of linking when (linkable) decisions tend to infinity, relying largely on the logic of the law of large numbers. To our knowledge, the current paper is the first to characterize the precise welfare benefit of linking a fixed (finite) number decisions (albeit with continuum of agents).

The rest of the paper is organized as follows. We present the formal model and welfare criterion in Section 3, provide welfare comparison across the three alternative procedures in Section 4. Section 5 presents simulation to quantify the welfare benefits of CADA. Section 6 then considers the implication of enriching the message used in the CADA and the robustness of our results to some students not behaving in a strategically sophisticated way. Section 7 concludes.

3 Model and Basic Analysis

3.1 Primitives

There are \( n \geq 2 \) schools, \( S = \{1, \ldots, n\} \), each with a unit mass of seats to fill. There are mass \( n \) of students who are indexed by vNM values \( \mathbf{v} = (v_1, \ldots, v_n) \in \mathcal{V} := [0,1]^n \) they attach to the \( n \) schools. The set of student types, \( \mathcal{V} \), is equipped with a measure \( \mu \). We assume that \( \mu \) is absolutely continuous with strictly positive density in the interior of \( \mathcal{V} \).

Let \( \tau^k \) be any ordered list of any \( k \) schools, and let \( \Pi^k \) be the set of all such ordered lists of \( k \) schools, with their union denoted \( \Pi := \bigcup_{k=1}^{n} \Pi^k \). Let \( \pi^k(\mathbf{v}) \) be the type \( \mathbf{v} \)-student’s \( k \) most preferred schools (listed in the descending order of her preferences). Let \( m_{\tau^k} := \mu(\{\mathbf{v} \in \mathcal{V} | \pi^k(\mathbf{v}) = \tau^k\}) \) be the measure of students whose ordinal preferences are \( \tau^k \). By the full support assumption, \( m_{\tau^k} > 0 \) for each \( \tau^k \in \Pi^k \forall k \leq n \). Hence, for each \( i \in S \), \( m_i = \mu(\{\mathbf{v} \in \mathcal{V} | \pi^1(\mathbf{v}) = i\}) \) represents the measure of students whose most preferred school

\[\text{See also Che and Gale 1998 and 2000 for the effect of budgetary limits in mechanism design.}\]
is $i$. It is useful to define the set

$$S^{**} = \{i \in S | m_i \geq m_j \forall j \in S\}$$

of most popular school(s).

Finally, let $m := \{m_{\tau}\}_{\tau \in \Pi^n}$ be a profile of measures of all ordinal types. Let $\mathcal{M} :=\{\{m_{\tau}\}_{\tau \in \Pi^n}| \sum_{\tau \in \Pi^n} m_{\tau} = n\}$ be the set of all possible measure profiles. The set $\mathcal{M}$ has $n! - 1$ dimensions. We say a property holds generically if it holds for a subset of $m$’s that has the same Lebesgue measure as $\mathcal{M}$.

An assignment, denoted by $x$, is a probability distribution over $S$, and this is an element of a simplex, $\Delta := \{(x_1, ..., x_n) \in \mathbb{R}_+^n| \sum_{i \in S} x_i = 1\}$. We are primarily interested in how a procedure determines the assignment for each student ex ante prior to conducting the lottery. To this end, we define an allocation to be a measurable function $\phi := (\phi_1, ..., \phi_n) : \mathcal{V} \mapsto \Delta$ such that $\int \phi_i(v) d\mu(v) = 1$ for each $i \in S$, with the interpretation that student $v$ is assigned by mapping $\phi = (\phi_1, ..., \phi_n)$ to school $i$ with probability $\phi_i(v)$. Let $\mathcal{X}$ denote the set of all allocations.

### 3.2 Welfare Standards

We begin with two standard notions of ex ante welfare. To begin, we say allocation $\tilde{\phi} \in \mathcal{X}$ weakly Pareto-dominates allocation $\phi \in \mathcal{X}$ if, for almost every $v$,

$$\sum_{i \in S} v_i \tilde{\phi}_i(v) \geq \sum_{i \in S} v_i \phi_i(v), \quad (1)$$

and that $\tilde{\phi}$ Pareto-dominates $\phi$ if the former weakly dominates the latter and the inequality of (2) is strict for a positive measure of $v$’s. We also say $\tilde{\phi} \in \mathcal{X}$ ordinally-dominates $\phi \in \mathcal{X}$ if, for a.e. $v$,

$$\sum_{i \in \pi^k(v)} \tilde{\phi}_i(v) \geq \sum_{i \in \pi^k(v)} \phi_i(v), \forall k = 1, ..., n - 1, \quad (2)$$

with the inequality being strict for some $k$, for a positive measure of $v$’s.

**Definition 1.** (i) An allocation $\phi \in \mathcal{X}$ is Pareto efficient (PE) if there is no other allocation in $\mathcal{X}$ that Pareto-dominates $\phi$.

(ii) An allocation $\phi \in \mathcal{X}$ is ordinally efficient (OE) if there is no other allocation in $\mathcal{X}$ that ordinally-dominates $\phi$.

For our purpose, it is useful to introduce additional welfare notions, those relating to the scope of efficiency. To begin, fix an assignment $x \in \Delta$, and a subset $K \subset S$ of schools. An assignment $\tilde{x} \in \Delta$ is said to be a within $K$ reassignment of $x$ if $\tilde{x}_j = x_j$ for each $j \in S \setminus K$,
and let $\Delta^K_x \subset \Delta$ be the set of all such reassignments. Then, a within $K$ reallocation of an allocation $\phi \in X$ is an element of a set

$$X^K_\phi := \{ \tilde{\phi} \in X | \tilde{\phi}(v) \in \Delta^K_{\phi(v)}, \text{ a.e. } v \in V \}.$$ 

In words, a within-$K$ reallocation of $\phi$ represents an outcome of students trading their shares of schools only within $K$.

**Definition 2.** (i) For any $K \subset S$, an ex ante allocation $\phi \in X$ is **Pareto efficient (PE) within** $K$ if there is no within $K$ reallocation of $\phi$ that Pareto dominates $\phi$.

(ii) For any $K \subset S$, an ex ante allocation $\phi \in X$ is **ordinally efficient (OE) within** $K$ if there is no within $K$ reallocation of $\phi$ that ordinal-dominates $\phi$.

(iii) An allocation is **pairwise PE** (resp. **pairwise OE**) if it is PE (resp. OE) within every $K \subset S$ with $|K| = 2$.

These welfare criteria are quite intuitive. Suppose the students are initially endowed with ex ante shares $\phi$ of schools but they can trade these shares amongst them. Can they trade mutually beneficially if the trading is restricted to the shares of $K$? The answer is no if allocation $\phi$ is **PE within** $K$. In other words, the size of the latter set represents the restriction on the trading technologies and thus determines the scope of markets within which efficiency is realized. The bigger the set is, the less restricted the agents are in the scope of trading, so it means a more efficient allocation. Clearly, if an allocation is Pareto efficient within the set of all schools, then it is fully Pareto efficient. In this sense, we can view the size of such set as a measure of efficiency.

A similar intuition holds with respect to ordinal efficiency. In particular, ordinal efficiency can be characterized by the inability to form a cycle of traders who beneficially swap their probability shares of schools. Formally, let $\triangleright^\phi$ be the binary relation on $S$ defined by

$$i \triangleright^\phi j \iff \exists A \subset V, \mu(A) > 0, \text{ s.t. } v_i > v_j \text{ and } \phi_j(v) > 0, \forall v \in A,$$

and say that $\phi$ admits a trading cycle within $K$ if there exist $i_1, i_2, \ldots i_l \in K$ such that $i_1 \triangleright^\phi i_2, \ldots, i_{l-1} \triangleright^\phi i_l$, and $i_l \triangleright^\phi i_1$. The next lemma is then adapted from Bogomolnaia and Moulin (2001).

**Lemma 1.** An allocation $\phi$ is OE within $K \subset S$ if and only if $\phi$ does not admit a trading cycle within $K$.

Before proceeding further, we observe how different notions relate to one another.

**Lemma 2.** (i) If an allocation is PE (resp. OE) within $K'$, then it is is PE (resp. OE) within $K \subset K'$;
(ii) An allocation is OE within \( K \subset S \) if it is PE within \( K \).

(iii) For any \( K \) with \( |K| = 2 \), if an allocation is OE within \( K \), then it is PE within \( K \).

(iv) If an allocation is OE, then it is pairwise PE.

Part (i) follows since a Pareto improving within-\( K \) reallocation of constitutes a Pareto improving within-\( K' \) reallocation for any \( K' \supset K \). Likewise, a trade cycle within any set forms a trade cycle within its superset. Part (ii) follows since if an allocation is not ordinally efficient within \( K \), then it must admit a trading cycle within \( K \), which easily implies there being a Pareto improving reallocation. Part (iii) follows since, whenever there exist an allocation that is not Pareto efficient within a pair of schools, there must be two groups of agents who would benefit from swapping their probability shares of these schools, from which the allocation must admit a trade cycle within that pair. Part (iv) then follows form Part (iii).

These characterizations are tight. The converse of Part (iii) does not hold for any \( K \) with \( |K| > 2 \). In the example from the introduction, the DA allocation is OE but not PE. Likewise, an allocation that is PE within \( K \) need not be OE within any \( K' \supseteq K \). To see this, imagine a situation in which an allocation is Pareto improvable upon only via a trade cycle that includes a school in \( K' \setminus K \). In that case, the allocation may be PE within \( K \) yet it will not be OE within \( K' \).

### 3.3 Alternative School Choice Procedures

We consider three alternative procedures for assigning students to the schools: (1) Deferred Acceptance with Single Tie-breaking (DA-STB), (2) Deferred Acceptance with Multiple Tie-Breaking (DA-MTB), and (3) Choice-Augmented Deferred Acceptance (CADA). These procedures, introduced earlier, can be extended to the continuum of students in a natural way.

The alternative procedures differ only by the way the schools break ties. The tie-breaking rule is well-defined for DA-STB and DA-MTB, and it follows Step 2 of Section 2 in the case of CADA, except that these rules must be extended to our continuous economy model. The formal descriptions are provided in Appendix A. Here, we offer the following heuristic descriptions:

- **DA-STB**: The mechanism draws a single random number \( \omega \in [0, n] \) for each student, and a agent with a lower number has a higher priority than the ones with higher numbers for each school.
• **DA-MTB:** For each student, the mechanism draws \( n \) independent random numbers \((\omega_1, \ldots, \omega_n)\) from \([0, n]^n\). The \( i \)-th component, \( \omega_i \), of student’s random draw then determines her priority at school \( i \), with a lower number draw having a higher priority than a higher number.

• **CADA:** The mechanism draws two random numbers \((\omega_T, \omega_R)\) for each student. School \( i \) then ranks those students who picked that school for their target, based on their \( \omega_T \) draws and then ranks the others based on \( \omega_R \) draws (with a lower number having a higher priority in both cases).

For each procedure, the DA algorithm is readily defined using the appropriate tie-breaker and the students’ ordinal preferences as inputs. Appendix A provides a precise algorithm, which is sketched here. At the first step, each student applies to her most preferred school. Every school \( i \) tentatively admits up to unit mass from its applicants in the order of its priority order, and reject the rest if there is any. In general, each student who was rejected in the previous step applies to her next preferred school. Each school considers the set of students it has tentatively admitted and the new applicants. It tentatively admits up to unit mass from these students in the order of its priority, and rejects the rest. The process converges when the set of students that are rejected has zero measure. Although this process might not complete in finite time, it converges in limit, and the allocation in the limit is well defined (see Theorem 10 of Appendix A). Further, each of the procedure is ordinally strategy proof:

**Theorem 1.** (Ordinal strategy-proofness) In each of the three procedures, it is a (weak) dominant strategy for each student to submit her ordinal preferences truthfully.

*Proof:* The proof follows from Theorem 11 in Appendix A.

### 3.4 Characterization of Equilibria

□ **DA-STB and DA-MTB**

The DA-STB process induces a cutoff \( c_i \in [0, n] \) for each school \( i \) such that a student who ever applies to school \( i \) gets assigned to that school if and only if her (single) draw \( \omega \) is less than \( c_i \). The existence of such a cutoff follows from the fact that an applicant with a lower draw can never be rejected by a school in favor of another applicant with a higher draw. Therefore, in equilibrium each school has a cutoff in \([0, n]\), and the \( n \) cutoffs can be listed in an ascending order as \((\hat{c}_1, \ldots, \hat{c}_n)\), with \( \hat{c}_i \leq \hat{c}_j \) for \( i < j \). (The order may be weak since the cutoff may be the same for several schools, in which case we simply repeat the same number.) It is useful to establish that these cutoffs are uniquely determined by \( m := \{m_{\tau}\}_{\tau \in \Pi^n} \) and all distinct generically:
Lemma 3. The cutoffs for the schools under DA-STB are uniquely determined by \( \mathbf{m} \), and satisfies \( \hat{c}^1 > 0 \) and \( \hat{c}^n = n \). The most popular school(s) in \( S^{**} \) have the lowest cutoff \( \hat{c}^1 \). For a generic \( \mathbf{m} \), the cutoffs are all distinct.

DA-MTB is similar to DA-STB, except that each student has independent draws \((\omega_1, ..., \omega_n)\), one for each school. The DA process again induces a cutoff \( c_i \in [0, n] \) for each school \( i \) such that a student who ever applies to school \( i \) gets assigned to it if and only if her draw for school \( i, \omega_i \), is less than \( c_i \). While the cutoffs under DA-STB are typically different from those under DA-MTB, we must have at least one school whose cutoff is equal to \( n \).\(^{11}\) We call such a school the “worst” school. (There is no presumption that the worst school under DA-STB is also the worst school under DA-MTB.)

\( \square \) CADA

As with the two other procedures, given the students’ strategies on their messages, the DA process induces cutoffs for the schools, one for each school in \([0, 2n]\). Of particular interest is the equilibrium in the students’ choices of messages. Given Theorem 1, the only nontrivial part of the students’ strategy concerns her “auxiliary message.” Let \( \nu = (\nu_1, ..., \nu_n) : \mathcal{V} \mapsto \Delta \) denote the students’ mixed strategy, whereby a student with \( \mathbf{v} \) “names school \( i \) for her target” with probability \( \nu_i(\mathbf{v}) \). We first establishes existence of equilibrium.

Theorem 2. (Existence) There exists an equilibrium in pure strategies.

We say that a student applies to school \( i \) if she is rejected by all schools she lists ahead of \( i \) in her (truthful) ordinal list. We say that a student subscribes to school \( i \in S \) if she picks school \( i \) for her target and applies to that school during the DA process. (The latter event depends on where she lists school \( i \) in her ordinal list and the other students’ strategies as well as the outcome of tie-breaking). Let \( \hat{\nu}_i^*(\mathbf{v}) \) be the probability that a student \( \mathbf{v} \) subscribes to school \( i \) in equilibrium. We say a school \( i \in S \) is oversubscribed if \( \int \hat{\nu}_i^*(\mathbf{v})d\mu(\mathbf{v}) \geq 1 \) and undersubscribed if \( \int \hat{\nu}_i^*(\mathbf{v})d\mu(\mathbf{v}) < 1 \). In equilibrium, there will be at least (generically, exactly) one undersubscribed school which anybody can get in, if she fails to get an any other schools she lists ahead of that school. Formally, a school \( w \in S \) is said to be “worst” if its cutoff on \([0, 2n]\) equals precisely \( 2n \). Then, we have the following lemma.

Lemma 4. (i) Any student who prefers the worst school the most is assigned to that school with probability 1 in equilibrium. (ii) If her most preferred school is undersubscribed but

\(^{11}\)If all cutoffs are strictly less than \( n \), then there is a positive measure of students who are never assigned to any school. There must be a school with its capacity unfilled, so that school’s cutoff cannot be less than \( n \), a contradiction.
not the worst school, then she names that school for her target in equilibrium. (iii) For almost every student with \( v \) such that \( \pi_1(v) \neq w, \nu^*(v) = \nu^*(v) \) in equilibrium.

In light of Lemma 4-(iii), we shall refer to “picks a school \( i \) as target” simply as “subscribes to school \( i \).”

4 Welfare Analysis of Alternative Procedures

We compare ex ante welfare of three alternative procedures in this section. We begin with DA-STB.

Theorem 3. (DA-STB) (i) In the DA-STB allocation, \( \phi^S \), the most popular school \( i \in S^{**} \) is assigned only to the students who prefer that school the most.

(ii) \( \phi^S \) is OE, and is thus pairwise PE.

(iii) For a generic \( m \), there exists no \( K \subset S \) with \(|K| > 2\) such that \( \phi^S \) is PE within \( K \).

These results are explained via Figure 1.

Following Lemma 3, the cutoffs of the schools are deterministic, as depicted in the figure. Suppose \( i \succ \phi^S j \). Then, there must exist a positive measure of students who prefer school \( i \) to school \( j \) but are assigned to \( j \) with positive probability. It must then follow that \( c_i < c_j \). Or else, any students who prefer school \( i \) can never be assigned to \( j \). This is because any such student will rank \( i \) ahead of \( j \) (by strategyproofness), so if she is rejected by \( i \), her draw must be \( \omega > c_i \geq c_j \), not good enough to get assigned to \( j \). Since the cutoffs are (at least weakly) ordered, this means that \( \phi^S \) cannot admit a trading cycle. Hence, it is OE (and thus pairwise PE). The same logic also implies that the most popular school can only be assigned to those who prefer it the most (as is claimed in Part (i)).

Most important, pairwise PE is, according to Part (iii), the most one can expect from DA-STB. In otherwise, DA-STB produces no better ex ante efficiency performance than is explainable by its ordinal efficiency. To see Part (iii), recall from Lemma 3 that the schools’ cutoffs are generically distinct. Take any set \( \{i, j, k\} \) with \( c_i < c_j < c_k \).
Then, by the full support assumption, there exists a positive measure of $v$’s satisfying $v_i > v_j > v_k > v_l$ for all $l \neq i, j, k$. These students will then have the positive chance of being assigned to each school in $\{i, j, k\}$, for their draws will land in the intervals, $[0, c_i], [c_i, c_j]$ and $[c_j, c_k]$, with positive probabilities. Again, given the full support assumption, such students will all differ in their marginal rate of substitution among the three schools. Then, just as with the motivating example, one can construct a mutually beneficial trading of shares of these schools among these students.

**Remark 1.** With finite students, the allocation from DA-STB is ex post Pareto efficient but is not OE, but as the number of students and school seats grow to our limiting model, the DA-STB allocation becomes arbitrarily close to being OE. This is an implication of Che and Kojima (2008), who show that the random priority rule (which coincides with our DA-STB) becomes indistinguishable from the probabilistic serial mechanism (which is known to be OE) as the economy grows large. When the schools have inherent priorities, the DA-STB is not even ex post Pareto efficient (Abdulkadiroglu et al., 2007).

Next, consider the DA-MTB. Let school $w \in S$ be the worst school if its cutoff under DA-MTB is $n$. There exists only one worst school for a generic $m$.

**Theorem 4.** (DA-MTB) (i) For $n \geq 3$, a positive measure of seats at each school are assigned to some students who do not prefer that school the most.

(ii) The allocation from DA-MTB is PE within $\{i, w\}$ for each $i \in S \setminus \{w\}$.

(iii) Generically, there exists no $K \subset S \setminus \{w\}$ with $|K| > 1$ such that the allocation from DA-MTB is OE within $K$.

(iv) Generically, there exists no $K \subset S$ with $|K| > 2$ such that the allocation from DA-MTB is OE within $K$.

The main results follow from the failure of ex post Pareto efficiency in the DA-MTB. This can be explained as follows. Take any two schools $\{i, j\}$, each of which is not a worst school. Type $i$ student may have a good draw at school $j$ but a bad draw at school $i$ (e.g., $(\omega_i, \omega_j)$ in Figure 3); and the opposite may occur to a type $j$ student (e.g., $(\omega'_i, \omega'_j))$. 16
In this case, the former will be assigned to $j$ and the latter to $i$, so both students will benefit from swapping their assignments. This possibility arises with positive probability, so the allocation admits a trade cycle $i - j - i$, and fails to be pairwise OE or pairwise PE. To see Part (ii), suppose school $j = w$ is the worst school. Then, $c_j = n$. This means that any students assigned to school $i$ must prefer that school over school $w$. Hence, they can never be better off from any within-$\{i, w\}$ reassignment, so the allocation is PE within $\{i, w\}$ (by Lemma 2-(iii)).

Theorems 3 and 4 have an obvious implication.

**Corollary 1.** Assume $n \geq 3$. Then, for a generic $m$, a PE allocation never arises from the DA algorithm with either tie-breaking procedure.

We next turn to the CADA algorithm. The welfare properties of its allocation are characterized as follows.

**Theorem 5.** (CADA) (i) Any equilibrium allocation of CADA is OE, and is thus pairwise PE.

(ii) Any equilibrium allocation of CADA is PE within the set of oversubscribed schools.

(iii) If all but one schools are oversubscribed, then the equilibrium allocation of CADA is PE.

Theorem 5-(ii) and (iii) showcase the ex ante efficiency benefit associated with CADA. As mentioned earlier, the benefit parallels that of a competitive market. Essentially, CADA supports “competitive markets” for oversubscribed schools. Each student is given a “budget” of unit probability she can allocate across alternative schools with the naming of a target school. A given unit probability can buy different amounts of shares for different schools, depending on how many others name those schools. If a mass $z_i \geq 1$ students applies to school $i$, allocating a unit budget can only buy a share $1/z_i$. Hence, the relative congestion at alternative schools, or their relative popularity, serves as relative “prices” for
these schools. In a large economy, individual students take these prices as given, so the prices play the usual role of allocating resources efficiently. It is therefore not surprising that the proof follows the First Welfare Theorem.

Why are competitive markets limited only to oversubscribed schools? Why not undersubscribed schools? The reason has to do with that one can get into an undersubscribed school in two different ways: She can name it for her target, in which case she gets assigned to it for sure; alternatively, she can name an oversubscribed school but the school rejects her, in which case she may still get assigned to the undersubscribed school via the usual DA channel. This means that no single price system regulates the students’ assignments to the undersubscribed schools. Furthermore, a spill-over from the oversubscribed schools accounts for assignment of some students to these schools. Consequently, competitive markets do not extend to them.

Finally, Part (i) asserts ordinal efficiency for CADA. At first glance, this feature may be a little surprising in light of the fact that different priority lists are used by different schools. As is clear from DA-MTB, this feature is susceptible to ordinal inefficiency. This is not the case, however, in the equilibrium of CADA. To see this, observe first that any student who is assigned to an oversubscribed school with positive probability must strictly prefer it to any undersubscribed school (or else she should have secured assignment to the latter school by choosing it for her target). This means that we cannot have \( j \succ^* i \) if school \( j \) is undersubscribed and school \( i \) is oversubscribed. This means that if the allocation admits any trading cycle, it must be within oversubscribed schools or within undersubscribed schools. The former is ruled out by Part (ii) and the latter by the same argument as Theorem 3-(ii).

The characterization of Theorem 5 is tight in the sense that there is generally no bigger set that includes all oversubscribed schools and some undersubscribed school that supports Pareto efficiency.\(^\text{12}\)

\(^{12}\)To see this, suppose there are four schools, \( S = \{1, 2, 3, 4\} \), and four types of students \( V = \{v^1, v^2, v^3, v^4\} \), with \( \mu(v^1) = \frac{3-\varepsilon}{2}, \mu(v^2) = \frac{1+\varepsilon}{2}, \mu(v^3) = \frac{3-\varepsilon}{2}, \) and \( \mu(v^4) = \frac{1+\varepsilon}{2} \) where \( \varepsilon \) is a small number.

| \( j \) | \( v^1_j \) | \( v^2_j \) | \( v^3_j \) | \( v^4_j \) |
|-------|-------|-------|-------|
| 1     | 10    | 10    | 20    | 20    |
| 2     | 3     | 5     | 9     | 8     |
| 3     | 1     | 4     | 8     | 1     |
| 4     | 0     | 0     | 0     | 0     |

In this case, type 1 and 3 students subscribe to school 1, and type 2 and 4 students subscribe to school 2. More specifically, the allocation \( \phi^* \) has \( \phi^*(v^1) = \phi^*(v^3) = (\frac{1}{3-\varepsilon}, 0, \frac{2-\varepsilon}{2(3-\varepsilon)}, \frac{2-\varepsilon}{2(3-\varepsilon)}) \) and \( \phi^*(v^2) = \phi^*(v^4) = (0, \frac{1}{1+\varepsilon}, \frac{\varepsilon}{3(1+\varepsilon)}, \frac{\varepsilon}{2(1+\varepsilon)}) \). Although schools 1 and 2 are oversubscribed, this allocation is not PE within \( \{1, 2, 3\} \) since type 1 students can trade probability shares of school 1 and 3 in exchange for probability share at 2, with type 1 students. The allocation is not PE within \( \{1, 2, 4\} \) either, since type 3 students
Theorem 5 refers to an endogenous property of an equilibrium, namely the set of over/under-subscribed schools. We provide a sufficient condition for this property. Let

\[ S^* := \{ i \in S | m_i \geq 1 \} \]

be the set of popular schools which each cannot accommodate all the students who prefer them the most. Note that a most popular school must be popular, i.e., \( S^{**} \subset S^* \).

It is easy to see that every school in \( S^* \) must be oversubscribed in equilibrium. Suppose to the contrary that school \( i \in S^* \) is undersubscribed. Then, by Lemma 4-(ii), every student with \( v \) with \( \pi_1(v) = i \) must subscribe to \( i \), a contradiction. Since each school in \( S^* \) is oversubscribed, the next result follows from Theorem 5.

**Corollary 2.** Any equilibrium allocation of CADA is PE within the set \( S^* \) of popular schools.

Corollary 2 provides a sufficient condition for a school to be oversubscribed. But it is quite possible that a non-popular school can be oversubscribed in equilibrium. In particular, if all students have the same ordinal preferences, then \( |S^*| = 1 \), so Corollary 2 has no bite. Yet, the set of oversubscribed schools can be much bigger than \( S^* \) even in this case. We can provide some insight into this question, by introducing more structure into the preferences.

Suppose all students have the uniform ordinal preferences, with the schools indexed by the uniform ranking. Letting \( V_U := \{ v \in V | v_1 > ... > v_n \} \), the students will have the same ordinal preferences if \( \mu(V_U) = \mu(V) \). Define

\[ V_U^2 := \left\{ v \in V_U \mid \frac{\sum_{i=1}^{n} v_i}{n} < v_2 \right\}. \]

**Lemma 5.** Assume \( \mu(V_U) = \mu(V) \), then at least two schools are oversubscribed in the CADA equilibrium if \( \mu(V_U^2) \geq 1 \).

Full Pareto efficiency may be achieved in some cases.

**Corollary 3.** The equilibrium allocation of CADA is PE if (i) all but one schools are popular, or if (ii) \( n = 3 \) and all students have the same ordinal preferences and \( \mu(V_U^2) \geq 1 \) holds.

### 4.1 Comparison of Procedures

A three-way comparison emerges from the preceding analysis. It provides a formal sense in which the CADA yields a better outcome than DA-STB, which in turn yields a better can trade probability shares of school 1 and 4 in exchange for probability share at 2, with type 4 students. Therefore \( \{1, 2\} \) is the largest set of schools that support Pareto efficiency.
outcome than DA-MTB. In particular, if the allocation from DA-MTB is PE within \( K \subset S \), then so is the allocation from DA-STB, although the converse does not hold; and if the allocation from DA-STB is PE within \( K' \subset S \), then so is the allocation from DA-STB, although the converse does not hold.

Specifically, between the two DA algorithms, DA-STB assigns the seats of the most popular school to those who prefer it the most, whereas this never happens with any school under DA-MTB. Further, the allocation arising from DA-STB is PE within any two schools, whereas the allocation from DA-MTB generically fails to be PE within two schools unless they contain a worst school.

Meanwhile, the CADA allocation is Pareto efficient within a strictly bigger set of schools than the allocations from DA algorithms, if there are more than two popular schools. The following examples illustrate comparisons further.

**Example 1.** There are three schools, \( S = \{1, 2, 3\} \), and three types of students \( \mathcal{V} = \{v^1, v^2, v^3\} \), each with \( \mu(v^i) = 1 \).

<table>
<thead>
<tr>
<th></th>
<th>( v^1 )</th>
<th>( v^2 )</th>
<th>( v^3 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( j = 1 )</td>
<td>5</td>
<td>4</td>
<td>1</td>
</tr>
<tr>
<td>( j = 2 )</td>
<td>1</td>
<td>2</td>
<td>5</td>
</tr>
<tr>
<td>( j = 3 )</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

Notice that \( S^{**} = \{1\} \) and \( S^* = \{1, 2\} \). It follows from Corollary 3 that the allocation from CADA is Pareto efficient. More specifically, the equilibrium allocation is \( \phi^*(v^1) = \phi^*(v^2) = (\frac{1}{2}, 0, \frac{1}{2}) \) and \( \phi^*(v^3) = (0, 1, 0) \).

The allocation from DA-STB is PE within any pair of two schools: \( \phi^S(v^1) = \phi^S(v^2) = (\frac{1}{2}, 0, \frac{1}{3}) \) and \( \phi^S(v^3) = (0, \frac{2}{3}, \frac{1}{3}) \).\(^{13}\) This allocation is not Pareto efficient since student 1 can trade probability shares of schools 1 and 3 in exchange for probability share at school 2, with student 2.

The allocation from DA-MTB is \( \phi^M(v^1) = \phi^M(v^2) \approx (0.392, 0.274, 0.333) \) and \( \phi^M(v^3) \approx (0.215, 0.451, 0.333) \).\(^{14}\) This is not PE within \( \{1, 2\} \).

**Example 2.** There are three schools, \( S = \{1, 2, 3\} \), and two types of students \( \mathcal{V} = \{v^1, v^2\} \), assuming that each student has a single uniform draw from \([0, 3]\), the cutoff for school 1 is \( c_1 = 1.5 \), the cutoff for school 2 is \( c_2 = 2 \), and the one for school 3 is 3.

\(^{13}\) Assuming that each student has a uniform draw from \([0, 3]\) for each school separately, the cutoff for school 1 is \( c_1 = \frac{\sqrt{7}}{2} \approx 1.177 \), the cutoff for school 2 is \( c_2 \approx 1.354 \), and the one for school 3 is 3.
with \( \mu(v^1) = 2 \) and \( \mu(v^2) = 1 \).

<table>
<thead>
<tr>
<th></th>
<th>( v_j^1 )</th>
<th>( v_j^2 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( j = 1 )</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>( j = 2 )</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>( j = 3 )</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

In this case, \( S^* = S^{**} = \{1\} \). Yet, it follows from Corollary 3 that the allocation from CADA is Pareto efficient. More specifically, the allocation \( \phi^* \) has \( \phi^*(v^1) = (\frac{1}{2}, 0, \frac{1}{2}) \) and \( \phi^*(v^2) = (0, 1, 0) \).

DA-STB and DA-MTB entail the same allocation \( \phi^{DA}(v^1) = \phi^{DA}(v^2) = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3}) \), which is PE within any pair of two schools. (The result of Theorem 4-(iii) does not hold for DA-MTB because the full-support assumption does not hold here.) This allocation is not PE since type 1 students can trade probability shares of school 1 and 3 in exchange for probability share at 2, with type 2 students.

Example 3. There are three schools, \( S = \{1, 2, 3\} \), and two types of students \( V = \{v^1, v^2\} \), each with \( \mu(v^1) = 2 \) and \( \mu(v^2) = 1 \).

<table>
<thead>
<tr>
<th></th>
<th>( v_j^1 )</th>
<th>( v_j^2 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( j = 1 )</td>
<td>10</td>
<td>10</td>
</tr>
<tr>
<td>( j = 2 )</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>( j = 3 )</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

In this example, the allocation arising from CADA is not PE. All students subscribe to school 1 in equilibrium, so the allocation \( \phi^* \) is \( \phi^*(v^1) = \phi^*(v^2) = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3}) \), just as with DA-STB and DA-MTB.

In fact, if all students have the uniform ordinal preferences (i.e., \( \mu(V) = \mu(V^U) \)), then we can show that the CADA (weakly) Pareto-dominates the DA.

Theorem 6. Suppose all students have the same ordinal preferences. The equilibrium allocation of CADA (weakly) Pareto dominates the allocation arising from DA with any random tie-breaking rule. If \( \mu(V^U_2) > 0 \), then there exists a positive measure of students who are strictly better off from the CADA algorithm.

5 Simulations

The theoretical results in the previous sections do not speak to the magnitude of efficiency gains or loses in each mechanism. In this section, we numerically investigate these questions via simulations, which also help highlight the sources of efficiency gains and loses.
In our numerical model, we have 5 schools each with 20 seats and 100 students. Student $i$’s vNM value for school $j$, $v_{ij}$, is given by

$$v_{ij} = \alpha u_j + (1 - \alpha)u_{ij}$$

where $\alpha \in \{0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9\}$, $u_j$ are common across students and $u_{ij}$ is specific to student $i$ and school $j$. We will say that correlation among preferences increases as $\alpha$ increases. For each $\alpha$, we draw $\{u_j\}$ and $\{u_{ij}\}$ uniformly randomly and independently from the interval $[0, 1]$ to construct student preferences. The similarity among student preferences increases as $\alpha$ gets closer to 1. In the extreme cases, there is no correlation among preferences when $\alpha = 0$, and and students have the same cardinal preferences when $\alpha = 1$. Given a cardinal utility profile, we simulate DA-STB and DA-MTB, compute a complete information Nash equilibrium of CADA and the resulting CADA outcome. We repeat that 100 times by drawing a new set of vNM utility values for each $\alpha$. In addition, we solve for a first best solution, which is a utilitarian maximum for each set of vNM utility values. We compute welfare in an experiment as the average of the students’ expected utilities in that experiment.\(^\text{15}\)

In Figure 1, we compare the three mechanisms to the first best solution. We plot the welfare of each mechanism as the percentage of the welfare at the first best solution. Two observations emerge from this figure. First, The welfare generated by each mechanism follows a U-shaped pattern. Second, CADA outperforms DA-STB, which outperforms DA-MTB at every value of $\alpha$ and the gap in performance between CADA and the other mechanisms widens as $\alpha$ gets bigger. The intuition behind the U-shaped pattern can be explained by focusing on the extreme values of $\alpha$. When $\alpha = 0$, the expected number of students ranking a particular school as their first choice is close to the capacity at that school. As a result, all three mechanisms are likely to assign almost all students to their first choices and all three perform almost equally well when $\alpha = 0$. As $\alpha$ increases, more and more students start ranking a particular school as their first choice. Consequently, welfare starts decreasing as $\alpha$ increases. When $\alpha = 1$, all students have the same cardinal preferences so any matching, therefore any mechanism, is ex ante efficient. That explains the increase in welfare as $\alpha$ increases from moderate values to $\alpha = 0.9$. Figure 1 also exposes the welfare advantage of CADA. CADA outperforms DASTB and DAMTB for all values of $\alpha$. The welfare gain from CADA is smaller for $\alpha = 0$. Again this can be explained by the fact that most students are assigned to their first choices by each mechanism due to extreme dissimilarity in preferences. The welfare gain of CADA

\(^{15}\)See Appendix for a detailed explanation for the simulations and the computation of the numbers for the figures.
increases as $\alpha$ increases. This is due to the fact that competition for one’s first choice increases as $\alpha$ increases. At those instances, who gets his first choice matters. While DASTB and DAMTB determine this purely randomly, by incorporating students’ vNM values in their decision making for their target schools, CADA outperforms DASTB and DAMTB. Intuitively, if a student’s vNM value for a school increases, the likelihood of the student selecting that school as target in an equilibrium of CADA, therefore the likelihood of her getting that school, are expected to increase. This feature of CADA contributes to welfare gains. The following two figures also confirm this intuition. Finally, the gap in welfare across mechanisms shrinks at $\alpha = 0.9$. Again this can be explained by the fact that when preferences are extremely similar, i.e. $\alpha = 1$, every matching is efficient therefore the welfare generated by each mechanism converges to the first best welfare as $\alpha$ gets closer to 1.

Figure 2 gives further insight about the workings of the mechanisms. It shows the percentage of students getting their first choices under each mechanism. First, DA-MTB assigns significantly smaller numbers to first choices. This is due to the artificial stability constraints created by multiple tie breaking, which also explains the bigger welfare loss associated with DAMTB. The patterns for CADA and DA-STB are more revealing. In particular, both assign almost the same number of students to their first choices for each value of $\alpha$. So, whereas the welfare differential in DAMTB can be explained by the decrease in the number of students getting their first choices, the difference among the other two can be explained partly by to which group of students the two mechanisms are assigning first choices more frequently. To this end, Figure 3 shows the the ratio of the mean utility of those who get their $k$-th choice under CADA to the mean utility of those who get their $k$-th choice under DA-STB at the realized matchings, for $k = 1, 2, 3$. Accordingly, those who get their $k$-th choice achieve a higher utility under CADA than under DASTB for each $k = 1, 2, 3$. Note the much more emphasized difference for the receivers of second choice. As one’s vNM for her second choice increases, that is, as her second choice becomes a good alternative to her first choice, she is more likely to select her second choice as target in order to avoid stiff competition at her first choice. As a result, she is more likely to get her second choice, therefore those who get their second choices are more likely to achieve higher utility under CADA. This self-selection is demonstrated in Figure 3. The same is true for third choices as well, and more so as $\alpha$ gets larger, which is also demonstrated in the figure.

Figure 4 shows that the number of oversubscribed schools is larger on average than the number of popular schools. Note that the average number of oversubscribed schools is larger than 2 at all values of $\alpha$. Recalling our Theorems 2 and 5, DASTB is never Pareto efficient within a set of more than 2 schools, whereas CADA is Pareto efficient within the set
of oversubscribed schools. Then Figure 4 shows a greater scope of efficiency with CADA, another main source of efficiency gain in CADA in comparison to DASTB. It is also worth to note that the average number of oversubscribed schools exceeds 3 for $\alpha \leq 0.4$. This implies that some of the realized number of oversubscribed schools is equal to 4. At those instances, CADA achieves full Pareto efficiency.

The equilibrium behavior of students in Figure 5 shows that more students pick their lower ranked schools as target as $\alpha$ gets closer to 1. This monotone pattern in behavior can be explained by the extent of competition over schools. As $\alpha$, therefore similarity among preferences, increases, more students have the same school as first choice. Therefore competition for one’s first choice becomes more intense. This gives students incentive to compete for their second, third and even fourth choices by selecting them as their target school in CADA.\textsuperscript{16} This also explains the widening gap between the number of popular schools and the number of oversubscribed schools as $\alpha$ goes to 1 in Figure 4. Note that there exist some realizations of the vNM values with positive probability, under which some students pick their forth choices in equilibrium when $\alpha$ is large.

Next, we numerically investigate CADA when students have priorities at schools. To this end, we introduce schools priorities as follows: Each school has two priority classes, high priority and low priority. For each preference profile above, we assume that 50 students have high priority in their first choice and low priority in their other choices, 30 students have high priority in their second choice and low priority in their other choices, and 20 students have high priority in their third choice and low priority in their other choices.\textsuperscript{17} For easier reference, if a student has high priority at a school, we refer that school as that student’s neighborhood school. We compute a complete information Nash equilibrium of CADA. Furthermore, we simulate DASTB. In this case, however, priorities introduce inefficiency, that is the matching produced by DASTB or CADA does not need to be student-optimal. Therefore, after computing a DASTB outcome, we find a student optimal stable matching that Pareto dominates the outcome of DASTB via Erdil and Ergin’s (forthcoming) stable improvement cycles algorithm, which we refer as the DASTB+SIC outcome.

In Figure 6, we compare CADA, DASTB and DASTB+SIC to the first best solution which maximizes the sum of utilities by ignoring priorities. We plot the welfare of each mechanism as the percentage of the welfare at the first best solution. Accordingly, CADA outperforms DA-STB for all values of $\alpha$. DASTB+SIC outperforms CADA up to $\alpha = 0.4$. However, note that this comes at the expense of incentives, as there is no student-optimal and strategy-proof stable mechanism (Erdil and Ergin, forthcoming). When there is more similarity among preferences, that is $\alpha = 0.5$, CADA catches up with DASTB+SIC and

\textsuperscript{16}Note that it is never optimal to select the fifth(last) choice as target.

\textsuperscript{17}This assumption is in line with empirical observation in Boston.
outperforms it as $\alpha$ gets bigger. In fact, DASTB+SIC loses its advantage over DASTB as $\alpha$ gets bigger. This is due to the fact that the extent of inefficiency associated with DASTB diminishes as $\alpha$ goes to one. In particular, in the extreme case of $\alpha = 1$, every matching is student optimal so that the stable improvement cycles algorithm has no bite. In contrast, CADA allocates schools more efficiently than DASTB+SIC does for higher values of $\alpha$.

DASTB+SIC assigns more students to their first choices than CADA does for low values of $\alpha$. The difference vanishes for large values of $\alpha$. The equilibrium behavior of students under CADA is similar, more and more students pick their lower ranked schools as their target as $\alpha$ gets bigger.\(^{18}\) However, Figure 7 shows that more students utilize their target choice for their neighborhood schools. The intuition behind this result is subtle. As more and more students pick their lower ranked choices as their target in equilibrium, it becomes tougher to compete for lower ranked schools especially for students who do not have high priority in their lower ranked schools. In turn, those students pick their first choice more frequently, which is their neighborhood school. However, this increases the competition at first choice schools for students whose first choices are not their neighborhood schools. In turn, they pick their lower ranked neighborhood schools as their target. In equilibrium, more students pick their neighborhood schools as their target for larger values of $\alpha$.

In summary, some similarity among preferences is expected in real-life school choice programs. However, at those instances student optimality, therefore DASTB+SIC, has little bite in improving ex ante efficiency. At those instances, CADA allocates schools more efficiently from an ex ante point of view even though its outcome may be inefficient ex post. CADA achieves this efficiency gain without harming student incentives, whereas ex post student optimality necessarily implies the loss of strategy-proofness.

6 Discussion

6.1 Enriching the Auxiliary Message

The auxiliary message can be expanded to include more than one school, perhaps at the expense of some practicality. In general, the auxiliary message can include a rank order of schools up to $k \leq n$, with the tie broken in the lexicographic fashion according to this rank order: A student is reordered to be ahead of another one at the priority list of school $i \in S$ if and only if the former ranks it higher than the latter in the auxiliary message. We call the associated CADA a **CADA of degree** $k$.

It is worth noting that the CADA of degree $n$ coincides with the Boston mechanism if the schools have no priorities and if all students have the same ordinal preferences. Such

\(^{18}\)Additional graphs are available from the authors up on request.
an enriching of the auxiliary message does not alter the qualitative features of CADA. In particular, an argument analogous to that of Theorem 6 applies to CADA of any degree, which has a rather surprising implication:

**Theorem 7.** If all students have the same ordinal preferences and the schools have no priorities, then the Boston mechanism weakly Pareto dominates the DA algorithm. If \( \mu(V^U_2) > 0 \), then there exists a positive measure of students who are strictly better off from the Boston mechanism than from a DA algorithm with any random tie-breaking procedure.

Expanding the auxiliary message may complicate the deliberation on the part of students and may be practically cumbersome. The beauty of CADA is that the auxiliary message can be kept as simple as practically manageable, if necessary, to \( k = 1 \) as has been assumed before. What are the benefits from adding more schools in the message? Some observations are easy to make. First, enriching the message does not generally guarantee full Pareto efficiency. Consider Example 3 again. Allowing the students to include the second message, or even a third message, does not make any difference: All students will pick school 1 as their first target and school 2 as their second target, and the precisely the same allocation will arise in equilibrium (which also coincides with one arising from DA-STB). The enriching of message can have a second-order effect, though. The first example illustrates the benefit side.

**Example 4. (More is better)** There are 4 schools, \( S = \{1, 2, 3, 4\} \), and two types of students \( \mathcal{V} = \{v^1, v^2\} \), each with \( \mu(v^1) = 3 \) and \( \mu(v^2) = 1 \).

<table>
<thead>
<tr>
<th>( v^1_j )</th>
<th>( v^2_j )</th>
</tr>
</thead>
<tbody>

<td>1</td>
</tr>
<tr>
<td>( j = 4 )</td>
<td>0</td>
</tr>
</tbody>
</table>

With CADA of degree 1, all students subscribe to school 1, so the allocation is completely random with \( \phi^*(v^j) = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}) \), \( j = 1, 2 \). With CADA of degree 2, all students pick school 1 as their first target; but type 1 students pick school 2 as their second target whereas type 2 students pick school 3 as their second target. Consequently, the allocation becomes \( \phi^{**}(v^1) = (\frac{1}{4}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}) \) and \( \phi^{**}(v^2) = (\frac{1}{4}, 0, \frac{3}{4}, 0) \). This allocation \( \phi^{**} \) Pareto dominates \( \phi^* \), although the former is not Pareto efficient.

A richer message need not be always better. A richer message space generates more opportunities for a student to self select at different tiers of schools. But the alternative opportunities may work as substitutes and militate each other. For instance, an opportunity
to self select at a lower tier of schools may reduce a student’s incentive to self select at a higher tier of schools, even though the latter kinds of self selection may be more important from the social welfare perspective. This kind of “crowding out” arises in the next example.

**Example 5. (More is worse)** There are 4 schools, $S = \{1, 2, 3, 4\}$, and two types of students $V = \{v^1, v^2\}$, with $\mu(v^1) = 3$ and $\mu(v^2) = 1$.

</tbody>
</table>

Consider first CADA of degree 1. Here, all type 1 students choose school 1 as their target, and all type 2 students choose school 2 as their target. In other words, the latter type of students self select into the second popular school. The resulting allocation is $\phi^*(v^1) = (\frac{1}{3}, 0, \frac{1}{3}, \frac{1}{3})$ and $\phi^*(v^2) = (0, 1, 0, 0)$. The expected utilities are $EU^1 = 4.33$ and $EU^2 = 4$. In fact, this allocation is Pareto optimal.

Suppose now CADA of degree 2 is used. In equilibrium, type 1 students choose school 1 and 2 as their first and second targets, respectively. Meanwhile, type 2 students choose school 1 (instead of school 2!) as their first target and school 3 as their second target. Here, the opportunity for type 2 students to self select at a lower tier school (school 3) blunts their incentive to self select at a higher tier school (school 2). The resulting allocation is thus $\phi^{**}(v^1) = (\frac{1}{4}, \frac{1}{3}, \frac{11}{12}, \frac{1}{3})$ and $\phi^{**}(v^2) = (\frac{1}{4}, 0, \frac{3}{4}, 0)$, which yield expected utilities of $EU^1 = 3.75$ and $EU^2 = 4.25$. This allocation is not PE since type 2 students can trade probability shares of school 1 and 3 in exchange for probability share at 2, with type 1 students.

Even though $\phi^*$ does not Pareto dominate $\phi^{**}$, the former is PE whereas the latter is not. Further, the former is superior to the latter in the Utilitarian sense (recall that students’ payoffs are normalized so that they aggregate to the same value for both types): the former gives aggregate utilities of 17, the highest possible level, whereas the latter gives 15.5 (which is 0.5 above the level that would arise from random assignment).

The last example suggests that the benefit from enriching the message space is not unambiguous. This is a potentially important point. In practice, expanding a message space adds a burden on the parents to be strategically more sophisticated. Hence avoiding such a demand for strategic sophistication is an important quality for a procedure to succeed. This makes the simple CADA (i.e., of degree 1) quite appealing. That this practical benefit may not even involve a welfare sacrifice is reassuring about the simple CADA.
6.2 Strategic Naivety

Since CADA involves some “gaming” aspect, albeit limited to tie-breaking, a natural concern is that not all families may be strategically competent. This concern has arisen in the context of the Boston mechanism. It has been observed that some significant percentage of families have played suboptimal strategies, for instance, wasting their second top choices to schools that are so popular that students can get in those schools by listing them as top choices. Such mistakes may arise because of the lack of knowledge about how the system works or the difficulty with assessing how popular schools are. The same concern may arise with respect to CADA, in that some families may not understand well the role the auxiliary message plays in the system and/or they may not judge accurately how over/undersubscribed various schools will turn out.

It is thus important to investigate how the CADA will perform when some families are not strategically sophisticated. To this end, we consider students who are “naive” in the sense that they always name their most preferred schools for target in the auxiliary message. Naming the most preferred school appears to be a simple, but reasonable, choice when she/he is unsure about the popularity of alternative schools or unclear about the role the auxiliary message plays in the assignment. Such a strategy will indeed be a best response for many situations, particularly if the first choice is distinctively better than the rest of the choices, so it could be a good approximation. We assume that there is a positive measure of students who are naive in this way, and the others know the presence of these students and their behavior, and respond optimally against them. Surprisingly, the presence of naive students do not affect the main welfare results in a qualitative way.

**Theorem 8.** In the presence of naive students, the equilibrium allocation of CADA satisfies the following properties:

(i) The allocation is OE, and is thus pairwise PE.

(ii) The allocation is PE within the set \( K \) of oversubscribed schools.

(iii) If every student is naive, then the allocation is PE within \( K \cup \{l\} \) for any undersubscribed school \( l \in J := S \setminus K \).

Theorem 8-(i) and (ii) are qualitatively the same as the corresponding parts of Theorem 5, except for Part (iii) of Theorem 5.\(^{19}\) Of course, the set of oversubscribed schools need not be the same when some fraction of students are naive, so (even) these results do not admit direct comparison between the case of fully rational students and the current case. In particular, Theorem 8-(iii) does not mean that the Pareto efficient set of schools is larger.

\(^{19}\)Suppose there are three schools, \( S = \{1, 2, 3\} \), and three types of students \( V = \{v^1, v^2, v^3\} \), with \( \mu(v^1) = \mu(v^2) = \mu(v^3) = 1 \).
when all students are naive than when there are no naive students. When every student
is naive, the set of oversubscribed schools coincides with the set of popular schools. When
no students are naive, however, the former is always weakly larger than the latter and can
be strictly larger (Recall Examples 1 and 3).

Nevertheless, the efficiency statement is very similar. In particular, Lemma 4-(ii) re-
mains valid in the current context, implying that any popular schools must be oversub-
scribed here as well. Hence, the same conclusion as Corollary 2 holds.

**Corollary 4.** In the presence of naive students, the equilibrium allocation of CADA is PE
within the set $S^*$ of popular schools.

We also investigate numerically the impact of naive players on average welfare via
simulations. To this end, we assume that a certain number of students play naively and
select their first choice as their target schools. Other students play their best responses in
a complete information Nash equilibrium. We run this simulation with 50 naive students,
with 75 naive students and with 100 (all) naive students. Figure 7 reports the average
percentage welfare with respect to the first best with zero, 50, 75 and 100 (all) naive
students. The welfare patterns are similar. A bigger number of strategic players yields a
more efficient outcome. It is worth to note that CADA continues to outperform DA-STB
even when all players are naive.

### 6.3 CADA with “Safety Valve”

The preceding subsection has seen that the main welfare property of CADA remains valid
even when an arbitrary proportion of the student population behaves naively. This does
not mean, however, that naive students are not disadvantaged by the others who may make
strategic use of the message. It thus makes sense to provide an extra safeguard to those
who may feel unsure about how to play the CADA game. This can be done by augmenting

<table>
<thead>
<tr>
<th></th>
<th>$v^1_j$</th>
<th>$v^2_j$</th>
<th>$v^3_j$</th>
</tr>
</thead>
<tbody>
<tr>

<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

Suppose type 1 and 2 students are sophisticated while type 3 students are all naive. In this case, type 1
and 3 students submit school 1, and type 2 students submit school 2 as their target. Then, the resulting
ex ante allocation has $\phi^*(v^1) = \phi^*(v^3) = (\frac{1}{2}, 0, \frac{1}{2})$ and $\phi^*(v^2) = (0, 1, 0)$. Although schools 1 and 2 are
oversubscribed, this allocation is not PE since it will be Pareto improving for type 2 students to trade
probability share of school 2 in exchange for probability shares at schools 1 and 3, with type 3 (naive)
students. Therefore, Theorem 5-(iii) does not extend to the case in which we have both sophisticated and
naive students.
the message space to allow for an “exit option” and to treat those who invoke such an option as if they are participating in the standard DA algorithm. Specifically, the CADA can be modified as follows.

- All students submit ordinal preferences and auxiliary messages. In the auxiliary message, a student can name a target school or say “Opt Out.”

- Random ordering of students are generated according to the standard method (e.g., STB). Then, run DA-STB using this priority list. (If a school has inherent priorities, the random list is used only to break a tie within the same priority class.) Assign those who have picked “Opt Out” according to this procedure.

- Assign the remaining students to the remaining seats, using the CADA algorithm. Specifically, construct the choice-augmented priority list for each school, as described before (using two random lists). Then, the assignment is made via the DA algorithm using the choice-augmented priority.

Clearly, this modified algorithm gives each student the option of achieving precisely the same lottery of assignments as she receives from the DA-STB. But she can choose to send an active signal and do better.

**Theorem 9.** The CADA with the safety option makes every student (weakly) better off than he/she is from the DA-STB.

### 6.4 Dynamic Implementation

As noted, the welfare benefit of CADA originates from the competitive markets it induces. Unlike the usual markets where there are explicit prices, however, in the CADA-generated markets, students’ beliefs about the relative popularity of schools act as the prices. Hence, for the CADA to have the desirable welfare benefit, the students beliefs must be reasonably accurate. In practice, the students’ preferences tend to reflect the reputations that schools have developed; thus, as long as the school reputations are stable, they can serve as reasonably good proxies for the prices. Nevertheless, the students may not share the same beliefs and the beliefs may not be accurate, in which case CADA procedure will not implement the CADA equilibrium precisely.

The CADA equilibrium can be implemented more precisely by making the (shadow) prices more explicit and by facilitating students’ ability to respond to them. Suppose, after submitting their ordinal preferences (which is an once and for all decision), the students can be asked to submit their auxiliary message in a dynamic fashion.
In Round 1, the students submit the names of their target schools. At the end of Round 1, the students are allowed to see the population distribution of target school choices.\textsuperscript{20} In Round \( m \geq 2 \), the students are allowed to change their auxiliary messages. If the number of students who have changed their auxiliary messages from the previous round is less than some (pre-specified) threshold, then their choices in Round \( m \) become final, and CADA is run, just as before, to produce a matching. If the number exceeds the threshold, then the population distribution of choices is announced, and they move on to Round \( m + 1 \).

Under this dynamic mechanism, a student’s choice matters only when most of the other students do not alter their choices. It is thus optimal for students to simply best respond to the announced distribution of population choices in the previous round. Clearly, the resulting best-response dynamics will lead to a Nash equilibrium (i.e., a CADA equilibrium discussed earlier), whenever the process converges. Although our dynamic process likely converge in practice, activity rules can be added to facilitate the convergence. For instance, limit cycles can be eliminated by preventing some small fraction of randomly selected students from returning back to their original choices after deviating from them once or twice.

7 Conclusion

In this paper, we propose a new deferred acceptance procedure in which students are allowed, via signaling of their preferences, to influence how they are treated in a tie for a school. This new procedure, choice-augmented DA algorithm (CADA), makes the most of two existing procedures, the Gale-Shapely’s deferred acceptance algorithm (DA) and the Boston mechanism. While the DA achieves the strategyproofness, an important property in the design of school choice programs, it limits students’ abilities to communicate their preference intensities, which entails an ex ante inefficient allocation when schools are indifferent among students with the same ordinal preferences. The Boston mechanism, on the other hand, is responsive to the agents’ cardinal preferences and may achieve more efficient allocation than the DA, but fails to satisfy strategyproofness. We show that, by allowing students to influence tie-breaking via additional communication, CADA implements a more efficient ex ante allocation than the standard DA algorithms, without sacrificing the strategyproofness of ordinal preferences.

\textsuperscript{20} Alternatively, the clearinghouse may compute and display the probabilities of assignment to different schools that would arise (from the CADA) from each choice, assuming that no other student alters her auxiliary message.

Appendix A: Extensions of Algorithms to the Continuous Environment

It is convenient to explicitly model the randomizing device used to break the ties. For our purpose, it is sufficient to consider a vector \( \omega = (\omega_1, ..., \omega_n) \in [0, n]^n =: \Omega \) of uniformly and independently generated numbers. (The vector of \( \omega \) will be sufficiently rich enough to model the procedures we study.) Formally, we augment the type space by incorporating the random draw to \( V \times \Omega =: \Theta \), with its generic element denoted \( \theta := (v, \omega) \), and endow it with a product measure \( \eta = \mu \times \xi_1 \times ... \times \xi_n \), where \( \xi_i \) is a uniform measure satisfying \( \xi([0, \omega_i]) = \frac{\omega_i}{n} \) for each \( \omega_i \in [0, n] \). This formalism avoids appealing to the law of large numbers (on the continuum of agents), by ensuring that a fraction \( \frac{\omega_i}{n} \) of the student mass draws \( \omega_i \) or less on each \( i \)-th random variable. A student of type \( \theta = (v, \omega) \) is then interpreted as having values \( v \) and drawing a vector \( \omega \). The student never observes \( \omega \), so her action required by the procedure will be measurable with respect to only \( v \); whereas (part or all of) \( \omega \) component is “discovered” by the schools for their use in tie-breaking.

An *ex post allocation* is a measurable function \( \psi := (\psi_1, ..., \psi_n) : \Theta \mapsto \Delta \) such that \( \psi_i(\theta) \in \{0, 1\} \) and that \( \int \psi_i(\theta) \eta(d\theta) = 1 \) for each \( i \in S \). Namely, \( \psi \) assigns a student with \( v \) to school \( j \) upon drawing \( \omega \) such that \( \psi_j(v, \omega) = 1 \). Let \( \mathcal{Y} \) be the set of all ex post allocations. Later, we shall describe how each procedure generates an ex post allocation. Some procedures may not use the entire vector of \( \omega \), so the ex post allocation they produce may be measurable with respect to only some components of \( \omega \).

We define the alternative DA procedures here.

**Ordinal preferences.** In any DA algorithm, every student submits a ranking of schools. Formally, students’ ordinal preferences are represented by a measurable function \( P : \Theta \rightarrow \Pi^n \), where \( P(v, \omega) \in \Pi^n \) is an ordered list of \( n \) schools (ordered not necessarily according to true preferences). Since the \( \omega \) is unobserved by the students (at least at the time of submitting the ordinal preferences), we require that \( P(v, \omega) = P(v', \omega') \) whenever \( v = v' \). We say a DA algorithm is *ordinally strategy-proof* if it is a (weak) dominant strategy for each student with \( v \) to choose \( P(v, \omega) = \pi^n(v) \).

**School priorities (tie-breaking rules).** We introduce a tie-breaker function which determines the priority of each student for each school as a function of the random draw (as well as their auxiliary message in the case of CADA), in the event of a tie. Formally, *tie-breaker function for school \( i \)* is a bounded measurable function \( F_i : \Theta \mapsto \mathbb{R} \), such that a student \( \theta' \) is interpreted as having a higher priority than student \( \theta \) if \( F_i(\theta') < F_i(\theta) \). A tie-breaker is a profile \( \mathcal{F} = \{F_i : i \in S\} \) of tie-breaker functions. Specifically, the tie-breakers for DA-STB, DA-MTB, and CADA are determined as follows:
• **DA-STB**: The STB rule uses the same tie-breaker function for all schools. This is modeled by a tie-breaker with

\[ F_i(v, \omega_1, ..., \omega_n) = \omega_1, \]

\[ \theta = (v, \omega_1, ..., \omega_n), \] for every school \( i \in S \). In other words, a draw’s draw \( \omega_1 \) serves as a priority number for all schools. Heuristically, a real number \( \omega_1 \) is drawn randomly from an interval \([0, n]\), for each student, which then serves as her priority score.\(^{21}\)

• **DA-MTB**: The MTB rule produce a randomly and independently drawn priority list for each school. This is modeled by a tie-breaker, with

\[ F_i(v, \omega_1, ..., \omega_n) = \omega_i, \]

for \( i \in S \) and for each \( \theta = (v, \omega_1, ..., \omega_n) \). In other words, for each student, a vector \((\omega_1, ..., \omega_n)\) of independent draws determines her priority scores at different schools.

• **CADA**: In CADA, each student sends an auxiliary message of a target school (in addition to their ordinal preferences over schools). Given a (measurable) strategy profile \( s: \mathcal{V} \to S \) determining the auxiliary message for each intrinsic type \( v \), the tie-breaker function for school \( i \) is given by

\[ F_i(v, \omega_1, ..., \omega_n) = \begin{cases} \omega_1 & \text{if } s(v) = i \\ n + \omega_2 & \text{if } s(v) \neq i \end{cases} \]

That is, under \( F_i \), ties are broken first in favor of students who report \( i \) as their target school, within them according to the random draw \( \omega_1 \), and then ties among the rest are broken according to a random draw \( \omega_2 + n \) (where \( n \) act as a “penalty score” \( n \)). Clearly, \( F_i \) is a measurable function since \( \omega_1 \) and \( s \) are measurable.

**Definition of DA algorithms**: Given ordinal preferences \( P \) and a tie-breaker \( \mathcal{F} = \{ F_i : i \in S \} \), a DA algorithm is defined as follows. First, we define a measurable function \( Ch_{F_i} \) over subsets of \( \Theta \) as the set of best ranked students for school \( i \in S \) according to \( F_i \) from a given set up to the capacity. Formally, for any measurable \( X \subset \Theta \), let

\[ Ch_{F_i}(X) := \sup\{ Y \subset X | \eta(Y) \leq 1, F_i(\theta) < F_i(\theta'), \forall \theta \in Y, \theta' \in X \setminus Y \} \]

denote the set of students chosen from \( X \) such that the set does not exceed the capacity and that the chosen students have a higher priority than those not chosen.

\(^{21}\)This heuristics invokes a law of large numbers, but our formal method does not rely on it for we assume a well-behaved randomization device.
Next, we define the $DA_F$ (deferred acceptance) mapping. Consider first a mapping $Q : \Theta \to \Pi$, where $Q(\theta)$ is an ordered list of any $k \leq n$ schools. (Recall $P(\theta)$ is a special case involving the full set of schools.) The DA mapping, $Q' = DA_F(Q) \in \Pi$ is determined as follows. Every student with $\theta$ applies to her most preferred school in $Q(\theta)$. Every school $i$ (tentatively) admits from its applicants in the order of $F_i$. If all of its seats are assigned, it rejects the remaining applicants. If a student $\theta$ is rejected by $i$, $Q'(\theta)$ is obtained from $Q(\theta)$ by deleting $i$ in $Q(\theta)$. If a student $\theta$ is not rejected, then $Q'(\theta) = Q(\theta)$. More formally, let $T_i(Q) = \{\theta \in \Theta : i \text{ is ranked first in } Q(\theta)\}$ be the set of students that rank $i$ as first choice. Note that $T_i(Q)$ is measurable. Then each school $i$ admits students in $Ch_{F_i}(T_i(Q))$ and rejects students in $T_i(Q) \setminus Ch_{F_i}(T_i(Q))$. If $\theta \in T_i(Q) \setminus Ch_{F_i}(T_i(Q))$ for some $i \in S$, then $Q'(\theta)$ is obtained from $Q(\theta)$ by deleting $i$ from the top of $Q(\theta)$; otherwise $Q'(\theta) = Q(\theta)$. Since $Q$ is a measurable function, $Q'$ is also measurable.

Repeated application of the $DA_F$ mapping gives us the DA algorithm. That is, given a problem $(P,F)$, let $Q^0 = P$ and define $Q^t = DA_F(Q^{t-1})$ for $t > 0$. Then $Q^t$ converges almost everywhere to some measurable $Q^*$ (Theorem 10 below). The matching can be then found by assigning $\theta$ to its top choice of $Q^*(\theta)$. Formally, define a mapping $\psi^{(P,F)} : \Theta \mapsto \Delta$ such that $\psi_i^{(P,F)}(\theta) = 1$ if $i$ is the top choice of $Q^*(\theta)$, and $\psi_i^{(P,F)}(\theta) = 0$ otherwise. Since the schools’ capacities are respected in each round and also in the limit, the mapping must be an ex post allocation.

We present two main results:

**Well-definedness of the Procedure.** The existence of $\psi^{(P,F)}$ follows from the next theorem.

**Theorem 10.** For every $(P,F)$, $DA_F(P)$ converges almost everywhere to some measurable $Q^* : \Theta \rightarrow \Pi$.

Proof. Define the set of rejected students as $R^t = \{\theta : \theta \in T_i(Q^t) \setminus Ch_{F_i}(T_i(Q^t))\}$ for some $i \in S$. Then $\eta(R^t)$ goes to zero as $t$ goes to infinity. Otherwise, if $\eta(R^t) \geq \kappa > 0$ for all $t$, all the schools in every student’s preference would be deleted in finite time because of finiteness of the number of schools, which in turn would imply that $\eta(R^t)$ goes to zero, a contradiction. Therefore, $DA_F(P)$ converges almost everywhere to some $Q^*$. Since every $Q^t = DA_F(P)$ is measurable, $Q^*$ is also measurable. 

**Ordinal Strategy-proofness.** Fix arbitrary ordinal preferences $P$. Let $P_{-v} : \mathcal{V} \setminus \{v\} \rightarrow \Pi^n$ denote the ordinal preferences of all students but $v$ determined by $P$. Recall that $\pi^n(v) \in \Pi^n$ represents the truthful ordinal preference induced by $v$, that is $\pi^n(v)$ lists $i$ before $j$ if and only if $v_i > v_j$. To simplify the notation, let $\psi^P := \psi^{(P,F)}$, with $F$ suppressed, and let $\psi^* := \psi^{(\pi^n(P_{-v}),F)}$ denote the matching outcome for any given type when it
submits its ordinal preferences truthfully and the others report $P$. When students report $P$, a student with type $v$ receives expected utility of

$$E_{\omega} [v \cdot \psi^P(v, \omega)].$$

**Theorem 11.** For every $(P, \mathcal{F})$, it is a (weak) dominant strategy for every student to submit her ordinal preferences truthfully to DA, that is, for all $v \in V$, $P$,

$$E_{\omega} [v \cdot \psi^*(v, \omega)] \geq E_{\omega} [v \cdot \psi^P(v, \omega)].$$

**Proof.** It suffices to show that, for all $\theta = (v, \omega)$,

$$v \cdot \psi^*(v, \omega) \geq v \cdot \psi^P(v, \omega).$$

Suppose to the contrary that

$$v \cdot \psi^*(v, \omega) < v \cdot \psi^P(v, \omega),$$

for some $\theta = (v, \omega)$ and $P$. We show that there exists a finite many-to-one matching problem for which a DA algorithm fails strategy-proofness, which will then constitute a contradiction to the standard strategy-proofness result (Dubins and Friedman, 1981; Roth, 1982).

To begin, fix any $K \in \mathbb{N}_+$, and construct a discretization of $(P, \mathcal{F})$ for $\theta$ as follows: For every $z = (z_1, ..., z_n)$ and $y = (y_1, ..., y_n)$ where $z_i, y_j \in \{0, ..., K\}$, consider a set

$$\Theta_{z,y} = \{(\tilde{v}, \tilde{\omega}) \in \Theta : \frac{z_i}{K} \leq \tilde{v}_i \leq \frac{z_i + 1}{K}, \frac{n y_j}{K} \leq \tilde{\omega}_j \leq \frac{n(y_j + 1)}{K}, i, j \in S\}.$$

Let $\eta_{K, \min} = \min_{\Theta_{z,y}} \eta(\Theta_{z,y})$, and let $\#\Theta_{z,y}$ be the integer part of $\frac{\eta(\Theta_{z,y})}{\eta_{K, \min}}$.

Pick $\#\Theta_{z,y}$ students in total from every set $\Theta_{z,y}$ at random without repetition. Let $\{\theta^l\}$ denote the set of students that are picked. If $\frac{\|\theta^l\|}{n}$ is not an integer, pick additional students from the larger sets until obtaining an integer $\frac{\|\theta^l\|}{n}$. Note that the number of additional students to be picked this way is less than $n$ and $n$ is fixed, therefore this will be negligible in the limit as $K$ goes to infinity. Now consider the problem in which the set $\{\theta^l\}$ of students are to be assigned to a set $S$ of schools each with capacity $\frac{\|\theta^l\|}{n}$. Each student $\theta^l = (v^l, \omega^l)$’s strict ordinal preference is given by $P(\theta^l)$. The schools’ strict preferences are given by $\mathcal{F}$. Denote this problem by $(\{\theta^l\}, S, P, \mathcal{F})_K$, and the associated ex post allocation $\psi^P_K$. As $K$ goes to infinity, $(\{\theta^l\}, S, P, \mathcal{F})_K$ approximate $(\Theta, S, P, \mathcal{F})$ arbitrarily closely. Hence, $\psi^P_K \rightarrow_{a.e.} \psi^P$ and $\psi^{\pi^P(v).P\rightarrow a.e.} \rightarrow_{a.e.} \psi^*$ as $K \rightarrow \infty$. Hence, if (3) holds, then there exists $K$ such that

$$v \cdot \psi^*_K(v, \omega) < v \cdot \psi^P_K(v, \omega).$$

This contradicts the fact that, in every finite problem, submitting true preferences to the student-proposing deferred acceptance mechanism is a dominant strategy for every student (Dubins and Friedman, 1981; Roth, 1982). \[ \]
Appendix B: Proofs of the Main Results

Proof of Lemma 3. Consider the first cutoff $\hat{c}^1$. Suppose this is the cutoff for school $i$. Take any student. If the student’s top choice is not $i$, then, if she ever gets to school $i$ — meaning she is turned down by schools she lists ahead of $i$ — then it means that her draw $\omega > c^1$, so she will never get into school $i$. This means that only students whose most preferred school is $i$ can only get assigned to school $i$. It then follows that $m_i \cdot \frac{\hat{c}^1}{n} = 1$, so $\hat{c}^1 = \frac{n}{m_i}$. For $\hat{c}^1$ to be the lowest cutoff, we must have $\hat{c}^1 = \frac{n}{\max_{i \in S} m_i}$. Hence, a most popular school has the lowest cutoff. We conclude that $\hat{c}^1$ is uniquely determined by $m$ (more precisely, by $\max\{m_i\}$, which is a function of $m$). Since $\max_{i \in S} m_i \ge 1$, $\hat{c}^1 \in (1, n]$.

We work recursively to define the rest of the cutoffs. Suppose that cutoffs $\{\hat{c}^j\}$, $j < k$, are uniquely determined by $m$ such that $\hat{c}^j \le \hat{c}^j \le n$ for all $1 \le i < j \le k - 1$. Let the cutoff $\hat{c}^j$, $j \le k - 1$, be the cutoff of school $\kappa(j) \in S$, where $\kappa : \{1, \ldots, k - 1\} \mapsto S$ is one-to-one. We now determine $\hat{c}^k$ uniquely as a function of $m$ and establish $\hat{c}^k \ge \hat{c}^{k-1}$. Let $S^{k-1} := \{j | j = \kappa(j') \text{ for some } j' \le k - 1\}$ be the associated set. Suppose that the cutoff $\hat{c}^k$ determines the cutoff of school $i \in S \setminus S^{k-1}$. Then, arguing as before, a student who prefers a school $j \in S \setminus (S^{k-1} \cup \{i\})$ to each school in $S^{k-1} \cup \{i\}$ never stands a chance to get in $i$. (Clearly, $\kappa$, $S^{k-1}$ and $\hat{c}^j$ all depend on $m$, which we suppress for convenience.)

For any nonempty subset $S' \subset S^{k-1}$, let $\hat{\Pi}(S')$ be the set of all permutations of $S'$. Let $\chi(S') := \{j \in S' | \kappa^{-1}(j) \ge \kappa^{-1}(j'), \forall j' \in S'\}$ be the school which has the highest index in $S^{k-1}$, meaning that $\chi(S')$ will be the school that has the largest cutoff among $S'$ (yet still has a lower cutoff than $\hat{c}^k$). Then, for school $i$ to have cutoff $\hat{c}^k$, the cutoff must be $\hat{c}^k = \hat{c}^k_i$, where $\hat{c}^k_i$ satisfies

$$m_i \cdot \frac{\hat{c}^k_i}{n} + \sum_{S' \subset S^{k-1}} \left[ \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \left( \frac{\hat{c}^k_i - \hat{\chi}(S')}{n} \right) \right] = 1,$$

or

$$\hat{c}^k_i = \frac{n + \sum_{S' \subset S^{k-1}} \left( \hat{\chi}(S') \left( \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \right) \right)}{m_i + \sum_{S' \subset S^{k-1}} \left( \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \right)}.$$

Let $\hat{c}^k := \min\{n, \min_{j \in S \setminus S^{k-1}} \hat{c}^j\}$, and $i = \kappa(k) := \arg \min_{j \in S \setminus S^{k-1}} \hat{c}^k_j$. Note that this definition conforms to the case of $k = 1$. We must have

$$m_i \cdot \frac{\hat{c}^k}{n} + \sum_{S' \subset S^{k-1}} \left[ \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \left( \frac{\hat{c}^k - \hat{\chi}(S')}{n} \right) \right] \le 1,$$

where the inequality holds with equality if $\hat{c}^k < n$. We next show that $\hat{c}^k \ge \hat{c}^{k-1}$. Suppose
to the contrary that $\hat{c}^k < \hat{c}^{k-1} \leq n$. We can rewrite (4) (with equality) as

$$m_i \cdot \frac{\hat{c}^k}{n} + \sum_{S' \subseteq S^{k-2}} \left[ \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \left( \frac{\hat{c}^k - \hat{c}(S')}{n} \right) \right] + 
\sum_{S' \subseteq S^{k-1}, S' \neq S^{k-2}} \left[ \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \left( \frac{\hat{c}^k - \hat{c}(S')}{n} \right) \right] = 1.$$

Hence,

$$m_i \cdot \frac{\hat{c}^k}{n} + \sum_{S' \subseteq S^{k-2}} \left[ \sum_{\tau \in \hat{\Pi}(S')} m_{(\tau,i)} \left( \frac{\hat{c}^k - \hat{c}(S')}{n} \right) \right] \geq 1,$$

from which it follows that $\hat{c}^k_i \leq \hat{c}^k < \hat{c}^{k-1}$, contradicting the definition of $\hat{c}^{k-1}$.

Let $l \in S \backslash S^{n-1}$ be the last school left. We prove $\hat{c}^n_l = n$. Recall

$$\hat{c}^n_l = \frac{n + \sum_{S' \subseteq S^{n-1}} \left[ \hat{c}(S') \left( \sum_{\tau \in \hat{\Pi}(S')} m(\tau,l) \right) \right]}{m_l + \sum_{S' \subseteq S^{n-1}} \left( \sum_{\tau \in \hat{\Pi}(S')} m(\tau,l) \right)}.$$  

(5)

The denominator of (5) measures of all students, so it equals $n$. The second term in the numerator of (5) becomes, when divided by $n$,

$$\sum_{S' \subseteq S^{n-1}} \left[ \hat{c}(S') \left( \sum_{\tau \in \hat{\Pi}(S')} m(\tau,l) \right) \right],$$

which measures all students who are assigned to $S^{n-1}$ and thus equals the sum of all terms on the left side of (4) across $k = 1, ..., n - 1$. It thus follows that

$$\sum_{S' \subseteq S^{n-1}} \left[ \hat{c}(S') \left( \sum_{\tau \in \hat{\Pi}(S')} m(\tau,l) \right) \right] \leq n - 1.$$  

(6)

Substituting (6) into (5) gives

$$\hat{c}^n_l \leq \frac{n + n(n - 1)}{n} = n.$$

To prove $\hat{c}^n_l = n$, suppose $\hat{c}^n_l < n$. Then, by monotonicity, $\hat{c}^k \leq \hat{c}^n \leq \hat{c}^n_l < n$, so (4) must hold with equality for all $k = 1, ..., n - 1$, which means that (6) must hold with equality. Therefore, $\hat{c}^n_l = n$, a contradiction. We conclude that $\hat{c}^n = \hat{c}^n_l = n$.

---

22 The denominator consists of measures of all students whose most preferred school is $l$, and of all the student whose second preferred school is $l$, and so on and so forth, thus telescoping to the sum of all students.
Although it is possible for $\hat{c}_k = \hat{c}_{k+1}$ for some $i = 1, \ldots, n - 1$, it is easy to see that this is not generic. If $\hat{c}_k = \hat{c}_{k+1}$, this means that there are $i \neq j$ such that $\hat{c}_i = \hat{c}_j$, which entails a loss of dimension for $m$ within $\mathcal{M}$. Hence, the Lebesgue measure of the set of $m$’s involving such a restriction is zero. It thus follows that $\hat{c}_i < \hat{c}_j$ if $i < j$ for a generic $m$. [Proof of Theorem 2. The proof is a direct application of Theorem 2 of Mas-Colell (1984).

Proof of Lemma 4. Part (i) follows trivially since such a student can name that school as the target and get assigned to it with probability one. To prove part (ii) consider any student of type $v$, whose values are all distinct. There are $\mu$-a.e. such $v$. Suppose her most preferred school $\pi_1(v) = i$ is undersubscribed and not a worst school. It is then her best response to pick $i$ as her target, since doing so can guarantee assignment to $i$ for sure, whereas choosing some other school as the target may result in assignment to some other school. Hence, the student must be choosing $i$ as her target in equilibrium.

To prove part (iii), consider any $v$ (with distinct values), such that $\pi_1(v) \neq w$. Suppose first $\nu^*_i(v) > 0$ for some undersubscribed school $i$. It follows from the above observation that her most preferred school must be an oversubscribed school (not necessarily $i$). Given the distinct values, she must strictly prefer school $i$ to all undersubscribed schools. Hence, she lists $i$ ahead of all undersubscribed schools in her ordinal list. Whenever she picks $i$, she will fail to place in any oversubscribed schools other than $i$ that she may list ahead of $i$, so she will apply to school $i$ with probability one. Suppose next $\nu^*_j(v) > 0$ for some undersubscribed school $j$. Then, the student must prefer $j$ to all other undersubscribed schools, so she will apply to $j$ with probability one whenever she fails to place in any oversubscribed school she may list ahead of $j$ in the ordinal list. Whenever she picks $j$ as her target, she is surely rejected by all oversubscribed schools she may list ahead of $j$, so she will apply to $j$ with probability one. We thus conclude that $\nu^*(v) = \bar{v}^*(v)$ for $\mu$-a.e. $v$. [Proof of Theorem 3:

Part (i): By definition, the most popular school has the lowest cutoff say $\hat{c}_1$. No student whose most preferred school is not the most popular school will never be assigned to that school, since whenever she fails to get into a more preferred school than the most popular school, she must have a draw $\omega > \hat{c}_1$.

Part (ii): Let $\psi^S$ be the ex post allocation arising from DA-STB. We show there is no ex post allocation that Pareto dominates $\psi^S$. To this end, list $S = \{i_1, \ldots, i_n\}$ in the ascending order of the equilibrium cutoffs of the scores (with the schools with the same cutoff listed in an arbitrary order), i.e., $i_k$ has a weakly lower cutoff than $i_l$ if $k < l$. Any
student assigned to a school say \(i_k \in S\) must have listed that school ahead of every school \(i_l\) with \(l > k\) (i.e., a weakly higher cutoff) in the ordinal ranking; or else, she could never have been assigned to \(i_k\). Given the ordinal strategyproofness (Theorem 11), almost all these students must be strictly worse off from being reassigned to any school \(i_j\) with \(l > k\). Suppose to the contrary that an ex post allocation, say \(\psi\), Pareto dominates \(\psi^S\). There must be a school \(i_k \in S\) such that a positive measure of \(\theta\)'s assigned to \(i_k\) under \(\psi^S\) must be assigned to some other school(s) under \(\psi\). Let \(i_{k^*}\) be such a school with the smallest cutoff index \(k^*\). Then, almost all types reassigned from \(i_{k^*}\) must be reassigned to school \(i_l\), with \(l > k^*\), under \(\psi\). Almost all such student type must be strictly worse off from the reassignment. Hence, \(\psi\) cannot Pareto dominate \(\psi^*\), a contradiction.

**Part (iii):** By Lemma 3, for a generic \(m\), the cutoff scores are distinct. Fix any such \(m\), and let \(c^1 < \ldots < c^n\) be the cutoff scores. Let \(\kappa : S \mapsto S\) be a permutation such that \(c^i = c^\kappa(i)\), and let \(\tau = (\kappa(1), \ldots, \kappa(n))\) be the resulting list of schools. Now consider the set of \(\mathcal{V}_\tau := \{v \in \mathcal{V} | v_{\kappa(i)} > v_{\kappa(j)} \text{ if } i < j\}\) student types that have the same preference order as \(\tau\). We first prove that any such student type has positive probability of assigning to every school in DA-STB. This can be shown as follows. By the full support assumption, \(m_\tau = \mu(\mathcal{V}_\tau) > 0\). For any school \(i \in S\), a student type \(v \in \mathcal{V}_\tau\) will be assigned to that school whenever her draw \(\omega\) lies in between \(\zeta^\kappa^{-1}(i)-1\) and \(\zeta^\kappa^{-1}(i)\) (let \(\zeta^0 \equiv 0\)), since her draw will not be low enough to get in any school she prefers but low enough to get in \(i\). Hence, her probability of getting assigned to school \(i\) is \(\frac{\zeta^\kappa^{-1}(i)-1}{n} > 0\) since the cutoffs are distinct.

Take any \(K = \{k_1, k_2, k_3\} \subset S\). We show that the DA-STB allocation \(\phi^S\) fails to be PE within \(K\). Consider again the student type \(v \in \mathcal{V}_\tau\). Without loss, \(v_{k_1} > v_{k_2} > v_{k_3}\) for any such type. By the above observation, \(\phi^S_k(v) > 0\) for \(i = 1, 2, 3\). By the full support assumption, there is a Pareto dominating within-\(K\) reallocation of \(\phi^S\) among the student types in \(\mathcal{V}_\tau\). Those with a high \(v_{k_2}\) relative to \((v_{k_1}, v_{k_3})\) sell shares at \((k_1, k_3)\) in exchange for an increased share at \(k_2\), with those with a low \(v_{k_2}\) relative to \((v_{k_1}, v_{k_3})\). We thus conclude that there exists no \(\hat{K}\) with \(|\hat{K}| = 3\) such that \(\phi^S\) is PE within \(\hat{K}\). The statement holds then by Lemma 2-(i) and (iii).

**Proof of Theorem 4:**

**Part (i):** For generic \(m\), there are at least two schools, say \(i\) and \(j\), whose cutoffs are strictly below \(n\), so a positive measure of those who prefer either of these schools the most are not assigned to that school. A positive measure of those who prefer \(i\) the most but not assigned to \(i\) have \(k \in S \setminus \{i\}\) as the second most preferred school and are assigned to it with positive probability. Similarly, a positive measure of those who prefer \(j\) the most but not assigned to \(j\) have \(i\) as the second most preferred school and are assigned to it
with positive probability. Hence, a positive measure of seats at every school are assigned to those who do not prefer that school the most.

**Part (ii):** Fix any \( i \in S \setminus \{w\} \). Any student who prefers school \( w \) to school \( i \), ranks \( w \) higher than school \( i \). Since \( w \) is the worst school with cutoff score \( n \), such a student is never assigned to school \( i \). Consequently, any students who are assigned to school \( i \) are those who prefer \( i \) to \( w \). Hence, almost all of those assigned to \( i \) under DA-MTB will be strictly worse off from getting reassigned \( w \). This proves that there is no within-\( \{i, w\} \) ex post reallocation of the DA-MTB allocation that Pareto dominates it. Hence, by Lemma 2-(iii), the DA-MTB allocation is OE and PE within \( \{i, w\} \) for any \( i \in S \setminus \{w\} \).

**Part (iii):** Choose any two schools \( \{i, j\} \) for \( i, j \in S \setminus \{w\} \). Generically, there are a positive measure of students whose best school is \( i \) and the second best is \( j \) and a positive measure of students whose best school is \( j \) and the second best is \( i \), respectively. Since neither school \( i \) nor \( j \) is a worst school, their cutoffs are strictly less than \( n \). Hence, a positive measure of the former type is assigned to school \( j \) and a positive measure of the latter type is assigned to school \( i \). Clearly, the allocation from DA-MTB is not OE within \( \{i, j\} \). The result follows from Lemma 2-(i) and (iii).

**Part (iv):** This part follows directly from Part (iii) since any three schools include two schools that are not the worst school and since generically there is only one worst school.

**Proof of Theorem 5:** Proof of Part (i) builds on that of part (ii), so it will appear last. Throughout, we let \( K \) and \( J \) be the sets of over- and under-subscribed schools.

**Part (ii):** Let \( \nu^*(\cdot) \) be an equilibrium, and let \( \phi^*(\cdot) \) be the ex ante allocation induced by \( \nu^*(\cdot) \). For any \( v \in V \), consider an optimization problem:

\[
[P(v)] \quad \max_{x \in \Delta^K(v)} \sum_{i \in S} v_i x_i
\]

subject to

\[
\sum_{i \in K} p_i x_i \leq \sum_{i \in K} p_i \phi_i^*(v),
\]

where \( p_i \equiv \max\{\int \nu_i^*(\tilde{v}) d\mu(\tilde{v}), 1\} \).

We first prove that \( \phi^*(v) \) solves \( [P(v)] \). This is trivially true for any \( v \) with \( \pi_1(v) = w \) since \( x_i = \phi_i^*(v) = 0, i \in K \) must hold by Lemma 3 (ii). Based on this observation, in the rest of the proof, we will restrict attention to students whose most preferred school is not the worst school.

Consider now any \( x \in \Delta^K(v) \) satisfying the constraint of \( [P(v)] \), and suppose a type \( v \)-student faces all others playing their parts of the equilibrium strategies \( \nu^* \) under the original CADA game. Consider a strategy called \( s_i \) in which she picks school \( i \in S \) as her
target in her auxiliary message and submits it as her top choice in her ordinal list, and
but submits truthful ordinal list otherwise. If type \( \mathbf{v} \) plays strategy \( s_i \), then she will be
assigned to school \( i \) with probability

\[
\frac{1}{\max\{\int \nu^*_i(\tilde{\mathbf{v}})d\mu(\tilde{\mathbf{v}}), 1\}} = \frac{1}{p_i}.
\]

If \( i \in J \), this probability is one. If \( i \in K \), then she will be rejected by school \( i \) with positive
probability. In that event, she will pass through the DA process according to her true
ordinal preferences, and will be assigned based on her non-target draw of score \( \omega_2 \). Since
she will never be assigned to any other schools in \( K \), she will only be assigned to a school in \( J \). Which school in \( J \) she is assigned to is determined solely by \( \omega_2 \) (holding fixed the
student’s ordinal rankings), and her draw of \( \omega_2 \) is independent of her draw of \( \omega_1 \) (which
determined her assignment to \( i \)). Hence, the conditional probability of a student getting
assigned to \( j \in J \), is the same, regardless of which oversubscribed school \( i \in K \) turned him
down. Note let that conditional probability be \( \tilde{\phi}^*_j(\mathbf{v}) \). Obviously, \( \sum_{j \in J} \tilde{\phi}^*_j(\mathbf{v}) = 1 \).

In summary, when playing \( s_i \), \( i \in K \) she will be assigned to school \( j \in J \) with probability

\[
\left(1 - \frac{1}{p_i}\right) \tilde{\phi}^*_j(\mathbf{v}).
\]

Suppose now the type \( \mathbf{v} \) student randomizes by choosing “strategy \( s_i \)” with probability
\( y_i := p_i x_i \), for each \( i \in K \), and with probability

\[
y_j := v^*_j(\mathbf{v}) + \left[ \sum_{i \in K} (v^*_i(\mathbf{v}) - p_i x_i) \left(1 - \frac{1}{p_i}\right) \right] \tilde{\phi}^*_j(\mathbf{v}),
\]

for each \( j \in J \). Observe \( y_j \geq 0 \) for all \( j \in S \). This is obvious for \( j \in K \). For \( j \in J \), this
follows since the terms in the square brackets are nonnegative:

\[
\sum_{i \in K} (v^*_i(\mathbf{v}) - p_i x_i) \left(1 - \frac{1}{p_i}\right) = \sum_{i \in K} (p_i \phi^*_i(\mathbf{v}) - p_i x_i) \left(1 - \frac{1}{p_i}\right)
\]

\[
= \left[ \sum_{i \in K} p_i (\phi^*_i(\mathbf{v}) - x_i) \right] - \left[ \sum_{i \in K} (\phi^*_i(\mathbf{v}) - x_i) \right]
\]

\[
= \sum_{i \in K} p_i (\phi^*_i(\mathbf{v}) - x_i) \geq 0,
\]

where the first inequality is implied by Lemma 3-(iii), the third equality holds since \( x \in \Delta^K_{\phi^*_i(\mathbf{v})} \), and the last inequality follows from the fact that \( x \) satisfies the constraint of \([P(\mathbf{v})]\).
Further,

\[
\sum_{i \in S} y_i = \sum_{i \in K} p_i x_i + \sum_{j \in J} \left[ \nu_j^* (v) + \left[ \sum_{i \in K} (\nu_i^* (v) - p_i x_i) \left( 1 - \frac{1}{p_i} \right) \right] \bar{\phi}_j^* (v) \right] \\
= \sum_{i \in K} p_i x_i + \sum_{j \in J} \nu_j^* (v) + \sum_{i \in K} \left[ (\nu_i^* (v) - p_i x_i) \left( 1 - \frac{1}{p_i} \right) \right] \left( \sum_{i \in J} \bar{\phi}_j^* (v) \right) \\
= \sum_{i \in K} p_i x_i + \sum_{j \in J} \nu_j^* (v) + \sum_{i \in K} \phi_i^* (v) - x_i \\
= \sum_{i \in S} \nu_i^* (v) = 1.
\]

The third equality holds since \( \sum_{i \in J} \bar{\phi}_i^* (v) = 1 \), the fourth is implied by Lemma 4-(iii), and the fifth follows since \( v \in \Delta^K_{\phi^* (v)} \), (which implies \( \sum_{i \in K} x_i = \sum_{i \in K} \phi^* (v) \)).

By playing the mixed strategy \( (y_1, ..., y_n) \), the student is assigned to school \( i \in K \) with probability

\[
\frac{y_i}{p_i} = x_i,
\]

and to each school \( j \in J \) with probability

\[
y_j + \left[ \sum_{i \in K} y_i \left( 1 - \frac{1}{p_i} \right) \right] \bar{\phi}_j^* (v) \\
= \nu_j^* (v) + \left[ \sum_{i \in K} (\nu_i^* (v) - p_i x_i) \left( 1 - \frac{1}{p_i} \right) \right] \bar{\phi}_j^* (v) + \left[ \sum_{i \in K} p_i x_i \left( 1 - \frac{1}{p_i} \right) \right] \bar{\phi}_j^* (v) \\
= \nu_j^* (v) + \sum_{i \in K} \nu_i^* (v) \left( 1 - \frac{1}{p_i} \right) \bar{\phi}_j^* (v) \\
= \nu_j^* (v) + \sum_{i \in K} \nu_i^* (v) \left( 1 - \frac{1}{p_i} \right) \phi_j^* (v) \\
= \nu_j^* (v) = x_j.
\]

In other words, the student \( v \) can replicate any \( x \in \Delta^K_{\phi^* (v)} \) that satisfies \( \sum_{i \in K} p_i x_i \leq \sum_{i \in K} p_i \phi_i^* (v) \) by playing a strategy available in the CADA game. Since \( \phi^* (\cdot) \) solves the CADA game and is still feasible in more constrained problem \( [P(v)] \), it must solve \( [P(v)] \). Moreover, since \( \mu \) is atomless and \( [P(v)] \) has a linear objective function on a convex set, \( \phi^* (v) \) must be the unique solution to \( [P(v)] \) for \( \mu \)-a.e. \( v \).
We prove the statement of the theorem by contradiction. Suppose to the contrary that there exists an allocation \( \phi(\cdot) \in X^K_\phi \) that Pareto dominates \( \phi^*(\cdot) \). Then, for \( \mu \)-a.e. \( v \), \( \phi(v) \) must either solve \( [P(v)] \) or violate the constraint. For \( \mu \)-a.e. \( v \), the solution to \( [P(v)] \) is unique and coincides with \( \phi^*(v) \). Therefore, we must have
\[
\sum_{i \in K} p_i \phi_i(v) \geq \sum_{i \in K} p_i \phi^*_i(v),
\]
for \( \mu \)-a.e. \( v \). Further, there must exist a set \( A \subseteq V \) with \( \mu(A) > 0 \) such that each student \( v \in A \) must strictly prefer \( \phi(v) \) to \( \phi^*(v) \), which must imply (since \( \phi^*(v) \) solves \( [P(v)] \))
\[
\sum_{i \in K} p_i \phi_i(v) > \sum_{i \in K} p_i \phi^*_i(v), \quad \forall v \in A.
\]
Combining (7) and (8), we get
\[
\int \sum_{i \in K} p_i \phi_i(v) d\mu(v) > \int \sum_{i \in K} p_i \phi^*_i(v) d\mu(v)
\]
\[
\Leftrightarrow \sum_{i \in K} p_i \int \phi_i(v) d\mu(v) > \sum_{i \in K} p_i \int \phi^*_i(v) d\mu(v).
\]
Now since \( \phi(\cdot) \in X \), for each \( i \in S \),
\[
\int \phi_i(v) d\mu(v) = 1 = \int \phi^*_i(v) d\mu(v).
\]
Multiplying both sides by \( p_i \) and summing over \( K \), we get
\[
\sum_{i \in K} p_i \int \phi_i(v) d\mu(v) = \sum_{i \in K} p_i \int \phi^*_i(v) d\mu(v),
\]
which contradicts (9). We thus conclude that \( \phi^* \) is Pareto optimal within \( K \).

Part (iii): Consider the following maximization problem for every \( v \in V \):
\[
[P(v)] = \max_{x \in \Delta} \sum_{i \in S} u_i x_i
\]
subject to
\[
\sum_{i \in K} p_i x_i \leq 1.
\]
When we have only one undersubscribed school, called school \( n \), the allocation \( x_n \) is completely pinned down by the allocation among \( n - 1 \) oversubscribed schools, that is,
\[
x_n = 1 - \sum_{i \in K} x_i.
\]
Therefore, an allocation $\mathbf{x} \in \mathcal{X}$ is feasible in CADA game if (and only if) (10) holds.

Now consider the following maximization problem:

$$\max_{\mathbf{x} \in \mathcal{X}} \sum_{i \in S} v_i x_i$$

subject to

$$\sum_{i \in K} p_i x_i \leq \sum_{i \in K} p_i \phi_i^*(\mathbf{v}). \quad (11)$$

Since $\phi^*(\cdot)$ solves less constrained problem $[P'(\mathbf{v})]$ and is still feasible in $[P'(\mathbf{v})]$, it must be an optimal solution for $[P'(\mathbf{v})]$. The rest of the proof is shown by the same argument as in Part (i).

**Part (i):** The argument in the text already established that the allocation cannot admit a trading cycle that includes both oversubscribed and unsubscribed schools. It cannot admit a trading cycle comprising only oversubscribed schools, since the allocation is PE within these schools, by Part (ii), making it OE within the schools, by Lemma 2-(ii). It cannot admit a trading cycle comprising only undersubscribed schools, since the logic of Theorem 3-(ii) implies that it is OE within undersubscribed schools. Since the allocation cannot admit any trading cycle, it must be OE.

**Proof of Lemma 5.** We can show that, if a school $j > 1$ is oversubscribed, then school $j - 1$ is oversubscribed. (Those who pick $j$ as target should have picked $j$, giving a contradiction.)

It then suffices to show that at least schools $\{1, 2\}$ are oversubscribed. Suppose not. Then, only school 1 is oversubscribed in equilibrium. Suppose mass $m_2 < 1$ of students pick school 2 as their target; and all other mass $n - m_2$ pick school 1 as their target. (No student picks school $j > 2$, since picking school 2 will guarantee enrollment, which dominates choosing any school $j > 2$.) Pick any student with $\mathbf{v}$ such that $\sum_{i=1}^{n} v_i < v_2$. If the student picks school 2, she can guarantee the payoff of $v_2$. If the student picks school 1, she can get

$$v_1 \frac{1}{n - m_2} + v_2 \frac{1 - m_2}{n - m_2} + \left( \sum_{i=3}^{n} v_i \right) \frac{1}{n - m_2} = \left( \sum_{i=1}^{n} v_i \right) \frac{1}{n - m_2} - v_2 \frac{m_2}{n - m_2},$$

which is less than $v_2$. Hence, all such students must be choosing 2 as their target. Since there is more than unit mass of such students, school 2 cannot be undersubscribed, which contradicts the hypothesis that only school 1 is oversubscribed.

**Proof of Theorem 6:** Consider first a DA algorithm with any random tie-breaking. Since all students submit the same rank order over schools, they all must be assigned to each school with the same probability. In other words, the allocation must be

$$\phi^{DA}(\mathbf{v}) = \left( \frac{1}{n}, \ldots, \frac{1}{n} \right) \text{ for all } \mathbf{v}.$$
Consider now CADA algorithm. Let $\nu^*(v) \in \Delta$ be the equilibrium mixed strategy adopted by type $v$. Then, a measure

$$\alpha_i^* := \int \nu_i^*(v) d\mu(v)$$

of students pick $i \in S$ for their target in equilibrium. The equilibrium induces a mapping $\varphi^*: S \mapsto \Delta$, whereby a student is assigned to school $j$ with probability $\varphi_j^*(i)$ if she picks $i$ for her target.

Since in equilibrium, the capacity of each school is filled, we must have, for each $j \in S$,

$$\sum_{i \in S} \alpha_i^* \varphi_j^*(i) = 1.$$  \tag{12}$$

That is, a measure $\alpha_i^*$ of students pick $i$ for their target, and a fraction $\varphi_j^*(i)$ of those is assigned to school $j$. Summing the product over all $i$ then gives the measure of students assigned to $j$, which must equal its capacity, 1.

Consider a student with any arbitrary $v \in V$. Suppose she randomizes in her auxiliary message by choosing school $i$ with probability

$$y_i := \frac{\alpha_i^*}{\sum_j \alpha_j^*} = \frac{\alpha_i^*}{n}.$$  

Then, the probability that she will be assigned to any school $k$ is

$$\sum_j y_j \varphi_k^*(j) = \sum_j \frac{\alpha_j^*}{n} \varphi_k^*(j) = \frac{1}{n},$$

where the second equality follows from (12). That is, she can replicate the same ex ante assignment with the randomization strategy as $\phi^{DA}(v)$. Hence, the student must be at least weakly better from CADA. This proves the first statement.

We next prove the second statement. There are two cases. Suppose first school 2 is undersubscribed. Then, each student with $v \in V^U_2$ can pick school 2 for her target and guarantee assignment to school 2. The resulting payoff, $v_2$, exceeds $\sum_{i \in S} \frac{v_i}{n}$ (since $v \in V^U_2$), so every such student must be strictly better off in CADA than in the DA and we are done. Suppose therefore school 2 is oversubscribed. Then, school 1 must be also oversubscribed. This means that $\alpha_2^* \in [1, n)$ in the CADA equilibrium.

[TO BE COMPLETED.]

**Proof of Theorem 8:** Part (i) is precisely the same as Part (i) of Theorem 5 and is the consequence of Part (ii) below and Part (ii) of Lemma 2 (which does not depend on whether the students are naive or not). Hence it is omitted. To prove Part (ii), it is useful
to establish the following lemma. As before, let $\phi^*$ denote the ex ante allocation arising from the CADA game and let $K$ and $J = S \setminus K$ be respectively the sets of oversubscribed and undersubscribed schools in equilibrium.

**Lemma N:** Any reassignment of $\phi^*(v)$ within $K$ will make a naive student with $v$ strictly worse off, for almost every $v$.

**Proof:** Consider a naive student with $v$. Assume without loss of generality that she prefers $i$ strictly over all other schools (i.e., $v_i > v_j, \forall j \neq i$). (This is without loss of generality since the values are distinct for almost every student type.) Since the student is naive, she subscribes to school $i$ with probability 1. If school $i$ is undersubscribed, then the result is trivial since $\phi^*_k(v) = 0$ for all $k \in K$. Hence, suppose school $i$ is oversubscribed. Then, any reassignment $x \in \Delta^K_{\phi^*(v)}$ must satisfy

$$\sum_{j \in K} x_j = \phi^*_i(v)$$

Since $v_i > v_j \forall j \neq i$, for any $x \in \Delta^K_{\phi^*(v)}, x \neq \phi^*_i(v)$, we must have

$$\sum_{j \in K} x_j v_j < \sum_{j \in K} x_j v_i = \phi^*_i(v) v_i,$$

which implies that the student must be strictly worse off from any such reassignment. ∥

We are now ready to prove Parts (ii) and (iii):

**Part (ii):** We make use of the proof of Theorem 5. By Lemma N, a type-$v$ naive student’s assignment from the CADA, $\phi^*(v)$, is a unique solution to $[P(v)]$, for a.e. $v$, even without the constraint

$$\sum_{i \in K} p_i x_i \leq \sum_{i \in K} p_i \phi^*_i(v). \quad (13)$$

Since $\phi^*(v)$ is feasible under (13), this must be a unique solution to $[P(v)]$.

For a non-naive student with a.e. $v$, the proof of Theorem 5 follows directly, so $\phi^*(v)$, is also a unique solution of $[P(v)]$. Since the equilibrium assignment of both types solves $[P(v)]$, the rest of the argument in the proof of Theorem 5 applies, proving that we $\phi^*$ is PE within $K$. ∥

**Part (iii):** Again let $\phi^*$ be the ex ante allocation arising from CADA. Suppose to the contrary that there exists a within-$K \cup \{l\}$ reallocation $\tilde{\phi}$ of $\phi^*$ that Pareto dominates $\phi^*$. By Part (ii), $\phi^*$ is PE within $K$, so $\tilde{\phi}_l(v) \neq \phi^*_l(v)$ for a positive measure of $v$, which in turn implies that there exists a set $A \subset V$ with $\mu(A) > 0$ such that $\tilde{\phi}_l(v) > \phi^*_l(v)$ for each
\( v \in A \). Since \( \bar{\phi}(v) \in \Delta_{\phi'(v)}^{K \cup \{l\}} \),
\( \sum_{j \in K \cup \{l\}} \bar{\phi}_j(v) = \sum_{j \in K \cup \{l\}} \phi'_j(v) \), so
\[
\sum_{j \in K} \bar{\phi}_j(v) < \sum_{j \in K} \phi'_j(v) \quad \text{for all } v \in A.
\]

Assume without loss that \( v \) satisfies \( v_i > v_j \) for all \( i \in K \) and for all \( j \neq i \). (\( i \neq l \) since \( \bar{\phi}_l(v) > \phi'_l(v) \) is impossible if \( i = l \).) Then, the type-\( v \) student’s expected payoff from \( \bar{\phi} \) is
\[
\sum_{j \in S} \bar{\phi}_j(v) v_j = \sum_{j \in K} \bar{\phi}_j(v) v_j + \bar{\phi}_l(v) v_l + \sum_{j \in J \setminus \{l\}} \phi'_j(v) v_j
\]
\[
< \sum_{j \in K} \bar{\phi}_j(v) v_i + \left( \bar{\phi}_l(v) - \phi'_l(v) \right) v_i + \phi'_l(v) v_l + \sum_{j \in J \setminus \{l\}} \phi'_j(v) v_j
\]
\[
= \left( \sum_{j \in K \cup \{l\}} \bar{\phi}_j(v) - \phi'_l(v) \right) v_i + \sum_{j \in J} \phi'_j(v) v_j
\]
\[
= \sum_{j \in S} \phi^*_j(v) v_j.
\]

Since this inequality holds for almost every \( v \in A \), and since \( \mu(A) > 0 \), \( \bar{\phi} \) cannot Pareto dominate \( \phi^* \).

**Appendix C: Simulations**

There are 5 schools each with a capacity of 20 seats and 100 students. Fix \( \alpha \). We independently draw 100 sets of vNM values for students. Let \( \{v^s_{ij}\} \) denote a draw of vNM values, where superscript \( s \) denote the draw and \( v^s_{ij} \) denotes student \( i \)’s vNM value for school \( j \).

Given a draw \( \{v^s_{ij}\} \), fix the mechanism, define the following: \( p^s_{ij} \) is the probability that student \( i \) is assigned school \( j \) under the mechanism. \( r^s_i(k) \) is the school that is ranked \( k \)-th in \( i \)’s preference list. \( P^s \) is the set of popular schools. \( O^s \) is the set of oversubscribed schools in an equilibrium of CADA with no naive players.

Given the mechanism, for each draw \( s \), we calculate the following:

\[
\bar{v}^s = \frac{1}{100} \sum_i \sum_j p^s_{ij} v^s_{ij}
\]

where \( \bar{v}^s \) is the mean utility of all students.

A first best or utilitarian maximum solves

\[
\bar{v}^s_{FB} = \frac{1}{100} \max_{\{p^s_{ij}\}} \sum_i \sum_j p^s_{ij} v^s_{ij}
\]
Let \( \{ \tilde{p}_{ij}^s \} \) denote a solution to the first best. There may be multiple solutions, we arbitrarily pick one.

Furthermore, we calculate

\[
\pi_i^1 = \frac{1}{100} \sum_i \sum_j p_{ij}^s \cdot 1(r_i(1) = j)
\]

where \( \pi_i^1 \) is the average probability of assigning a student her first choice.

In the CADA experiments with naive players, we divide the set of students into two: \( N \) is the set of naive players who always pick their first choice as target, and \( S \) is the set of strategic/sophisticated players who play their best response strategies given others’ strategies. We calculate the mean-utilities accordingly.

We also compute the number of students picking their \( k \)-th choice as their target school in equilibrium, which we denote by \( T_{ij}^k \), \( k \in \{1, 2, 3, 4\} \).

Given a draw \( \{ v_{ij}^s \} \), the set \( P^s \) is determined trivially. Next we describe how the other numbers are computed.

A single tie breaker is a list of 100 randomly drawn numbers, one for each student. Under DA-STB the ties at a school are broken according to students’ single random numbers. In CADA, we draw two single tie breakers, one to be used to break ties at one’s target school, the other to be used at one’s other schools. A multiple tie breaker is a list of \( 100 \times 5 = 500 \) randomly drawn numbers, one for each student at each school. Under DA-MTB, the ties at a school are broken according to students’ tie breaker numbers at that school.

For each draw \( \{ v_{ij}^s \} \), we independently draw 2,000 single tie breakers for DA-STB, and an additional set of 2,000 single tie breakers for CADA, and 2,000 multiple tie breakers for DA-MTB. Then \( p_{ij}^s \) for a mechanism is computed by

\[
\frac{\text{Number of tie breakers at which } i \text{ is assigned } j}{2,000}
\]

The equilibrium of CADA is computed with single tie breakers being fixed. Given the strategies of other students, a student’s best response is found by computing that student’s expected utility over those tie breakers. Then \( O^s \), the set of oversubscribed schools, is found by using students’ equilibrium target schools. In experiments with naive players, naive players’ target schools are fixed at their first choice.

Note that we are approximating the equilibrium by drawing (two sets of) 2,000 independent tie-breakers. The exact numbers are computed by considering 100! single tie-breakers and \((100!)^5\) multiple tie breakers, which is beyond the capabilities of our computational resources. Any further increase in the number of tie breakers beyond 2,000 does not increase the precision of our computations significantly. Also, we are picking an equilibrium arbitrarily from a set of possibly multiple equilibria.
For each \( z^s \in \{ v^s, v^s_{FB}, \pi_1^s, T_1^s, T_2^s, T_3^s, T_4^s, |P^s|, |O^s| \} \), we compute the average of \( z^s \) by

\[
    z = \frac{1}{100} \sum_{s=1}^{100} z^s
\]

Note that we drop all “\( s \)” from a variable to denote its mean over 100 iterations of an experiment.

We report \( 100 \frac{v}{v_{FB}} \) in our welfare figures.
