Should Robots Be Taxed?*

Joao Guerreiro†  Sergio Rebelo‡  Pedro Teles§

April 2020

Abstract

Using a quantitative model which features technical progress in automation and endogenous skill choice, we show that, given the current U.S. tax system, a sustained fall in automation costs can lead to a massive rise in income inequality. We characterize the optimal tax system in this model. We find that it is optimal to tax robots while the current generations of routine workers, who can no longer move to non-routine occupations, are active in the labor force. Once these workers retire, optimal robot taxes are zero.

1 Introduction

The American writer Kurt Vonnegut began his career in the public relations division of General Electric. One day, he saw a new milling machine operated by a punch-card computer outperform the company’s best machinists. This experience inspired his novel “Player Piano.” It describes a world where children take, at an early age, a test that determines their fate. Those who pass, become engineers and design robots used in production. Those who fail, have no jobs and live from government transfers. Are we converging to this dystopian world? How should public policy respond to the impact of automation on the demand for labor?

These questions have been debated ever since 19th-century textile workers in the U.K. smashed the machines that eliminated their jobs. As the pace of automation quickens and affects a wide range of economic activities, Bill Gates re-ignited this debate by proposing the introduction of a robot tax. Policies that address the impact of automation on the labor have been widely discussed, e.g., by the European Parliament, and have been implemented in countries such as South Korea.

In this paper, we use a model of automation to study whether it is optimal to tax robots. Our model has two types of occupations which we call routine and non-routine. Robots are complements to non-routine workers and substitutes for routine workers.

To build our intuition, we first consider a simple static model where workers have fixed occupations. In this model, a fall in the cost of automation increases income inequality by increasing the non-routine wage premium.

If the tax system allowed for different lump-sum taxes on different workers, then technical progress would always be welfare improving since the gains could be re-distributed. But these discriminatory taxes cannot be levied when the government...
does not observe the worker type.

For this reason, we solve for the optimal tax system imposing, as in Mirrlees (1971), the constraint that the government does not observe the worker type or the worker’s labor input. The government observes the worker’s income and taxes it with a non-linear schedule. In addition, robot purchases are also observed and taxed with a proportional tax.

In this Mirrleesian tax system, it is optimal to tax robots if the planner wants to redistribute income towards routine workers. By taxing robots, the planner decreases the non-routine wage premium and improves income redistribution. To redistribute, the planner seeks to give positive net transfers to routine workers. However, because the tax system is the same for all workers, the non-routine workers can choose the income-consumption bundle of routine workers. The bundle can be particularly attractive for non-routine, high-wage workers because they can earn the same level of income as routine workers in just a few hours. Taxing robots reduces the non-routine wage premium, which makes the routine bundle relatively less attractive. As a result, the planner can provide a better bundle to the routine workers. The optimal robot tax balances these benefits of wage compression with the inefficiency losses from distorting production.

This rationale for positive robot taxes differs from the one proposed by Bill Gates. Gates argued that robots should be taxed to replace the tax revenue from the routine jobs lost to automation. In our model, automation increases output and overall tax revenue so there’s no need to replace taxes on routine wages.

The benchmark model which we use in our quantitative work is a dynamic model with endogenous skill acquisition. This model has an overlapping-generations structure that incorporates life-cycle aspects of labor supply. Workers have heterogeneous costs of skill acquisition and choose either a routine or non-routine occupation before they enter the labor market.\(^3\) Once they enter the labor force they cannot adjust

\(^3\)Our model is related to a large literature on the importance of technology-specific human capital
their skill. They work and then retire.

The cost of producing robots falls over time as a result of technical progress. We choose parameters so that the status quo of the dynamic model is consistent with the time series for the non-routine wage premium and the fraction of the population with routine occupations in the U.S. economy. We show that, under the current tax system, a sustained fall in the cost of automation generates a large rise in income inequality and a substantial fall in the welfare of those who work in routine occupations.

We solve for the optimal Mirrleesian tax policy under perfect commitment. In this model, tax policy affects the skill acquisition choices made by the current newborn generation as well as future generations. For this reason, the question of whether robots should be taxed is more complex than in the static model. Initially, it is optimal for the planner to tax robots to help redistribute income towards routine workers of the initial older generations who are still in the labor force. These workers made their skill choices in the past, so they are not affected by the planner’s generosity. In contrast, the planner gives future routine workers a less generous allocation to provide incentives to acquire non-routine skills.

Implementing this policy requires commitment. The planner treats the initial generations, which can no longer change their skill choices, differently from the generations that will be making skill choices in the future. This time dependence of the optimal commitment solution is a source of time inconsistency. At every future date, the planner would benefit from revising the optimal commitment solution. This revision would involve taxing robots to redistribute more income towards routine workers.

We find that it is optimal to tax robots in the first three decades. During this period, the labor force still includes older workers that chose their occupation in the

\footnote{for the diffusion of new technologies, see for example, \textit{Chari and Hopenhayn} (1991), \textit{Caselli} (1999), and \textit{Adão, Beraja and Pandalai-Nayar} (2018).}
past. The optimal robot tax is 7 percent in the first decade, 3 percent in the second decade, and 1 percent in the third decade. Once the initial generations retire, the optimal robot tax is zero.

The paper is organized as follows. In Section 2, we discuss the related literature. In section 3, we describe a simple static model of automation. In Section 4, we analyze the benchmark, dynamic model of automation with endogenous skill acquisition. Section 5 develops the quantitative analysis of this dynamic model. Section 6 concludes. To streamline the main text, we relegate the more technical proofs to the appendix.

2 Related literature

Our results on optimal robot taxes follow from well-known principles of optimal taxation in the public-finance literature. The classic result in this literature is the production-efficiency theorem of Diamond and Mirrlees (1971). According to this theorem, taxing intermediate goods is not optimal even when the planner has to use distortionary taxes. Since robots are an intermediate good, our result that it is optimal to tax robots represents a failure of the production-efficiency theorem.

Why does this theorem fail in our setting? The theorem requires the ability to tax net trades of different goods at different linear rates. In other words, the planner must have enough independent tax instruments to affect every relative price in the economy. In our model, this restriction means that the labor income of different types of workers can be taxed at different rates, even when those workers earn the same income. We do not allow for this form of tax discrimination. Instead, as in Mirrlees (1971), we require that all worker types face the same nonlinear tax schedule. Workers can only be taxed at different rates when they earn different incomes.

Given the restriction that all workers face the same tax schedule, it can be optimal to deviate from production efficiency. But this restriction is not sufficient to
justify deviating from production efficiency. Atkinson and Stiglitz (1976) show that production efficiency is still optimal in a Mirrlees (1971)-type model where labor types are perfect substitutes. In that setting, pretax relative wages are exogenous, so even if the planner does not have instruments to affect every relative price, distorting production does not help in affecting those prices to improve redistribution outcomes.

The result that, when labor types are imperfect substitutes, production efficiency may no longer be optimal was first shown by Naito (1999), building on the work of Stiglitz (1982) (see also Scheuer, 2014 and Jacobs, 2015). This result applies directly to our static model. Routine and non-routine workers are imperfect substitutes. Robots are substitutes for routine labor and complements for non-routine labor. By taxing robots, the planner can raise the pretax relative wage of routine workers through a general equilibrium effect.

We find that taxing robots can also be optimal in the benchmark, dynamic version of our model in which workers choose whether to be routine or non-routine. In allowing for endogenous skill choice, our approach is closely related to Saez (2004), Rothschild and Scheuer (2013), Scheuer (2014), Gomes, Lozachmeur and Pavan (2018), among others. These authors characterize Mirrlees-style optimal tax plans in static models with endogenous occupation choice.

---

4There is also a large literature that studies how the general-equilibrium effects on prices and wages first emphasized by Stiglitz (1982) affect the optimal shape of labor-income taxes. This literature includes, among others, Rothschild and Scheuer (2013), Scheuer (2014), and Ales, Kurnaz and Sleet (2015), Sachs, Tsyvinski and Werquin (2016).

5Scheuer and Werning (2016) clarify these results. Given that different levels of income in a Mirrleesian setup can be interpreted as different goods in the Diamond and Mirrlees setup, there is an equivalence between the two approaches. Since the Mirrleesian tax schedule is nonlinear, different labor incomes can be taxed at different rates. When there is a single occupation, i.e., when workers are perfect substitutes, the different goods (labor-income levels) are taxed at different rates and production efficiency is optimal. Instead, with multiple occupations, i.e., when workers are imperfect substitutes, different occupations that pay the same labor income are different goods. But these different goods have to be taxed at the same rate if there is a single nonlinear income-tax function. For this reason, production efficiency may cease to be optimal.
Saez (2004) shows that the production-efficiency theorem holds in a model in which the worker chooses the occupation, but labor supply is exogenous. Scheuer (2014), instead, considers a model with an endogenous labor supply in which agents choose whether to become workers or entrepreneurs. He finds that, in the absence of differential taxation for these two occupations, the optimal plan may feature production distortions, much like the ones we have in our model.

In our setup, since workers choose their labor hours as well as their skills, both intensive and extensive margins are potentially relevant. The robot tax is positive as long as the intensive-margin choice for the worker constrains the design of the optimal policy. If the planner only needs to provide incentives along the extensive margin, then production efficiency is optimal. In our calibrated economy, it is optimal to tax robots for the first three ten-year periods. The reason for this result is that the intensive margin is the only relevant margin for the initial old generations who cannot acquire new skills. Once these old workers retire, the optimal robot tax is zero because the only relevant margin for future young generations is skill choice.

Our results are related to the extensive literature on optimal capital taxation. This literature dates back to the seminal Chamley-Judd result that capital should not be taxed in the steady state (Chamley, 1986; Judd, 1985). Werning (2007) extends the Chamley-Judd result to a model in which workers are heterogeneous, but perfect substitutes in production. He shows that it is optimal not to distort capital accumulation both in the transition and in the steady state.

Our analysis is closest to that of Slavík and Yazici (2014), who consider optimal Mirrleesian taxation in an infinite-horizon model with low- and high-skill workers and capital-skill complementarity. They find that it is optimal to tax equipment capital in the steady state because it is a complement to high-skill workers and a substitute for low-skill workers. Optimal capital taxes are high initially and rise over

---

6Imperfect substitutability of labor types is also the reason why the optimal capital tax is positive in Jones, Manuelli and Rossi (1997) when the Ramsey tax system is the same for all workers.
time. The highest capital tax rate occurs in the steady state.

Despite our different applications, the reasons for taxing equipment capital in \textit{Slavík and Yazici} (2014) are very similar to the reasons why we find that robots should be taxed, the imperfect substitutability of labor types and the skill complementarity with either capital or robots. Our model differs from \textit{Slavík and Yazici} (2014)’s along two key dimensions: our analysis takes into account technical progress and endogenous skill acquisition. Because of these two elements, the reasons to deviate from production efficiency in our model cease to be relevant in the long run, so robot taxes eventually become zero.

In our model, robots are an intermediate good. We do not model robots as capital because a period in our model represents a decade. So, there is no time to build and robots depreciate fully. Time to build and partial depreciation are relevant for the optimal taxation of capital in ways that are not present in our model. However, if robots were a capital good, the reasons why production efficiency fails in our model would be the same reasons why the accumulation of robots would be distorted.\footnote{The literature on capital taxation has emphasized other motives for capital taxation which are not relevant for our analysis for the following reasons. First, \textit{Werning} (2007) shows that, in a Mirrleesian setting, there is no confiscation motive for future capital taxes. Second, our preference structure and assumptions about available instruments are such that the uniform taxation results of \textit{Atkinson and Stiglitz} (1972, 1976) apply. As a result, there is no reason to use capital taxes to introduce intertemporal distortions (see \textit{Chari and Kehoe}, 1999, and \textit{Chari, Nicolini} and \textit{Teles}, 2019). Third, we do not consider idiosyncratic income risk, so the reasons to tax capital discussed by \textit{Golosov, Kocherlakota} and \textit{Tsyvinski} (2003) are not present (see also \textit{Da Costa} and \textit{Werning}, 2002).}

In recent work, \textit{Thuemmel} (2018) and \textit{Costinot and Werning} (2018) also study optimal robot taxation.\footnote{Another related recent paper is \textit{Tsyvinski and Werquin} (2017). These authors generalize the idea of a compensating variation to an economy with general equilibrium effects and distortionary taxation. They use their formulas to describe the optimal changes to the tax system required to compensate the effects of automation, but abstract from the possibility of taxing automation directly.} The reason why it is optimal to tax robots in these papers is essentially the same as in our work. \textit{Thuemmel} (2018) considers a static Mirrleesian economy with three occupations: non-routine cognitive, non-routine manual, and routine workers. This model generates a richer set of implications for the
impact of automation on income inequality than a model with only one type of non-routine worker. Thuemmel also considers within-occupation wage heterogeneity, which is not present in our analysis. Despite these differences, Thuemmel’s quantitative findings are broadly consistent with ours. COSTINOT and WERNING (2018) consider a general static framework with a continuum of worker types. They derive optimal-tax formulas which depend on a small set of sufficient statistics that require relatively few structural assumptions. Using empirical estimates of these statistics, they find that small positive robot taxes are optimal. They also characterize a set of conditions under which the optimal robot tax decreases as automation progresses.

Our motivation for studying a dynamic overlapping-generations economy with skill acquisition comes in part from the work of ADÃO et al. (2018). Using an estimated structural model, these authors show that young and old generations respond differently to technical progress. They find weak responses of employment shares to changes in relative wages for old generations, but very strong responses for the newer generations. This empirical result suggests that the incentives of new generations to acquire skills are important in understanding how to optimally tax robots.

3 A static model

We first consider a static model of automation to address our optimal policy questions. The model has two types of workers that draw utility from consumption of private and public goods and disutility from labor. One worker type supplies routine labor and the other non-routine labor. The consumption good is produced combining both types of labor with robots. Robots and routine labor are used in a continuum of tasks.\footnote{See THUEMME (2018) for a static Mirrleesian economy with three worker types (non-routine cognitive, non-routine manual, and routine) and within-occupation wage heterogeneity.}

\footnote{See AUTOR, LEVY and MURNA (2003) for a study of the importance of tasks performed by routine workers in different industries and a discussion of the impact of automating these tasks on the demand for routine labor.}
**Workers** There is a continuum of unit measure of workers. The index $j$ denotes either non-routine, $j = n$, or routine workers, $j = r$. The fractions $\pi_n$ and $\pi_r$ of workers are non-routine and routine, respectively. A worker derives utility from consumption, $c_j$, and from the provision of a public good, $G$, and derives disutility from the hours of labor, $l_j$. The worker’s utility function is

$$U_j = u(c_j, l_j) + v(G).$$

We assume that the first and second derivatives satisfy $u_c > 0$, $u_l < 0$, $u_{cc}$, $u_{ll} < 0$. We also assume that consumption and leisure are normal goods, so that $u_{lc}/u_l - u_{cc}/u_c \geq 0$, and $u_{ll}/u_l - u_{cl}/u_c \geq 0$, with one of these conditions as a strict inequality. Finally, we assume that $v_G > 0$, $v_{GG} < 0$ and that $u(c, l)$ satisfies standard Inada conditions.

Worker $j$ chooses consumption and labor to maximize utility (1) subject to the budget constraint

$$c_j \leq w_j l_j - T(w_j l_j),$$

where $w_j$ denotes the wage rate received by the worker type $j$ and $T(\cdot)$ denotes the income-tax schedule.

**Robot producers** Robots are produced by competitive firms. It costs $\phi$ units of output to produce a robot. This cost is the same across all tasks. A representative robot-producing firm chooses robot supply, $X$, to maximize profits: $p_X X - \phi X$. It follows that in equilibrium $p_X = \phi$ and profits are zero.

**Final good producers** The representative producer of final goods hires non-routine labor ($N_n$), routine labor, and buys intermediate goods which we refer to as robots. Aggregate production follows a task-based framework which has become standard in the automation literature (ACEMOGLU and RESTREPO, forthcoming, 2019). There is a unit interval of tasks that can be performed by either routine labor or robots. The
services produced by these tasks are denoted by $y_i$ for each $i \in [0, 1]$. The production function is given by

$$
Y = A \left[ \int_0^1 \frac{\rho^{1-1}}{y_i^\rho} \, di \right]^\frac{\rho}{\rho-1} \left(1-\alpha\right) N_n^\alpha, \quad \alpha \in (0, 1), \quad \rho \in [0, \infty).
$$

(2)

Each task can be produced with $n_i$ workers or $x_i$ robots,

$$
y_i = \begin{cases} 
\kappa_i x_i, & \text{if } i \text{ is automated,} \\
\ell_i n_i, & \text{if } i \text{ is not automated.}
\end{cases}
$$

(3)

The parameters $\kappa_i$ and $\ell_i$ represent the efficiency of robots and routine labor, respectively, in task $i$. Without loss of generality, let $\kappa_i/\ell_i$ be weakly decreasing in $i$. This property implies that tasks are ordered such that routine workers are relatively more efficient in tasks indexed by higher values of $i$. Given this assumption, firms choose to automate the first tasks in the unit interval. We write the production function as:

$$
Y = A \left[ \int_0^m (\kappa_i x_i)^\frac{\rho-1}{\rho} \, di + \int_m^1 (\ell_i n_i)^\frac{\rho-1}{\rho} \, di \right]^\frac{\rho}{\rho-1} \left(1-\alpha\right) N_n^\alpha,
$$

(4)

where $m$ denotes the level of automation, i.e., the fraction of tasks executed by robots.

The firm’s problem is to maximize profits,

$$
Y - w_N N_n - w_r \int_0^1 \left(1 + \tau^x\right) \phi \int_0^m x_i \, di,
$$

where $Y$ is given by equation (4). The variable $\tau^x$ is the proportional tax rate on robots.

The optimal choices of $N_n, x_i$ for $i \in [0, m]$, and $n_i$ for $i \in (m, 1]$ require that the
following first-order conditions be satisfied:

\[ w_n = \frac{\alpha Y}{N_n}, \quad (5) \]

\[ (1 + \tau^x) \phi = \frac{(1 - \alpha)Y}{x_s} \left( \frac{\rho - 1}{\rho} \right) \frac{1}{\rho} x_s^{\frac{\rho - 1}{\rho}} \left( \int_0^m (\kappa_i x_i) \frac{\rho - 1}{\rho} di + \int_m^1 (\ell_i n_i) \frac{\rho - 1}{\rho} di \right), \quad (6) \]

\[ w_r = \frac{(1 - \alpha)Y}{n_s} \left( \frac{\rho - 1}{\rho} \right) \frac{1}{\rho} n_s^{\frac{\rho - 1}{\rho}} \left( \int_0^m (\kappa_i x_i) \frac{\rho - 1}{\rho} di + \int_m^1 (\ell_i n_i) \frac{\rho - 1}{\rho} di \right). \quad (7) \]

To simplify, we assume that \( \kappa_i = \ell_i = 1 \) for all \( i \), i.e., robots and routine workers are equally productive for all tasks. This assumption lends tractability and clarity to the exposition of our results.\(^{11}\) Section 4 relaxes this assumption in the context of the dynamic model.

Under this assumption, it is optimal to use the same level of routine labor, \( n_i \), in the \( 1 - m \) tasks that have not been automated and use the same number of robots in the \( m \) automated tasks:

\[ mx_i = X, \text{ for } i \in [0, m], \text{ and } (1 - m)n_i = N_r, \text{ for } i \in (m, 1], \quad (8) \]

where \( N_r \) denotes total routine hours and \( X \) denotes the total number of robots.

The optimal level of automation is zero, \( m = 0 \), if \( w_r < (1 + \tau^x)p_x \). The firm chooses to fully automate, \( m = 1 \), and to employ no routine workers if \( w_r > (1 + \tau^x)p_x \). If \( w_r = (1 + \tau^x)p_x \), the firm is indifferent between any level of automation \( m \in [0,1] \). In the latter case, equations (6) and (7) imply that the levels of routine labor and robots are the same across tasks.

In the case of an interior solution for the level of automation, we find that the optimal level of automation is \( m = X/(N_r + X) \). This result allows us to write the production function as \( Y = A \left( X + N_r \right)^{1-\alpha} N_n^\alpha \).

\(^{11}\)Under the assumption that \( \ell_i = \kappa_i = 1 \), our task-based production function coincides with the aggregate production function considered by Autor et al. (2003).
**Government** The government chooses taxes and the optimal level of government spending in order to satisfy the budget constraint

\[ G \leq \pi_r T(w_r l_r) + \pi_n T(w_n l_n) + \tau^x p_x X. \quad (9) \]

**Equilibrium** An equilibrium is a set of allocations \( \{c_r, l_r, c_n, l_n, G, N_r, X, x_i, n_i, m\} \), prices \( \{w_r, w_n, p_x\} \), and a tax system \( \{T(\cdot), \tau^x\} \) that: (i) solves the workers’ problem given prices and taxes; (ii) solves the firms’ problem given prices and taxes; (iii) satisfies the government budget constraint; and (iv) satisfies market clearing.

The market clearing conditions for routine and non-routine labor are

\[ N_j = \pi_j l_j, \quad j = n, r, \quad (10) \]

and the market-clearing condition for output is

\[ \pi_r c_r + \pi_n c_n + G \leq Y - \phi X. \quad (11) \]

**The equilibrium with interior automation** In an equilibrium with automation, the wage rate of routine workers equals the cost of robot use: \( w_r = (1 + \tau^x)\phi \). This condition implies that the number of robots used in each automated task equals the number of routine workers used in each non-automated task

\[ \frac{X}{m} = \frac{\pi_r l_r}{1 - m}. \]

Combining this equation with the firm’s first-order condition (6), we obtain

\[ (1 + \tau^x)\phi = (1 - \alpha)(X + \pi_r l_r)^{-\alpha}(\pi_n l_n)^\alpha. \quad (12) \]

Finally, replacing \( X = m\pi_r l_r / (1 - m) \) in equation (12), we find that the equilibrium level of automation satisfies

\[ m = 1 - \left[ \frac{(1 + \tau^x)\phi}{(1 - \alpha)A} \frac{\pi_r l_r}{\pi_n l_n} \right]^{1/\alpha}. \quad (13) \]
Furthermore, using equations (5) and (6), we find that the wages of both non-routine
and routine labor are given by technological parameters and $\tau^x$:

$$\begin{align*}
w_n &= \alpha A^{1/\alpha} \left[ \frac{1 - \alpha}{(1 + \tau^x)\phi} \right]^{\frac{1-\alpha}{\alpha}}, \\
w_r &= (1 + \tau^x)\phi.
\end{align*}$$

(14) (15)

The wage of routine workers is determined by the after-tax cost of robots. Because
of constant returns to scale, the ratio of inputs is pinned down and so is the wage of
the non-routine worker. An increase in $\tau^x$ raises the wage of routine workers and
lowers the wage rate of non-routine agents.

Production net of the cost of robots is given by

$$Y - \phi X = \pi_n w_n l_n \frac{\tau^x + \alpha}{\alpha(1 + \tau^x)} + \pi_r w_r l_r \frac{1 + \tau^x}{1 + \tau^x}.$$  

(16)

It is useful to note that the shares of routine and non-routine income in total
production are

$$\frac{w_r \pi_r l_r}{Y} = (1 - \alpha)(1 - m), \quad \text{and} \quad \frac{w_n \pi_n l_n}{Y} = \alpha.$$

An increase in automation reduces the income share of routine workers in total
production and leaves the share of non-routine workers unchanged. As the econ-
omy approaches full automation, non-routine workers earn all labor income. In this
sense, an increase in automation leads to an increase in pretax income inequality.

### 3.1 Status-quo equilibrium in the static model

In this section, we describe the status-quo equilibrium, that is, the equilibrium under
the current U.S. income tax system without robot taxes ($\tau^x = 0$). We model the U.S.
income tax system using the functional form for after-tax income proposed by Feld-
stein (1969), Persson (1983), and Benabou (2000) and estimated by Heathcote
et al. (2017). In this specification, the income tax paid by worker $j$ is given by
\[ T(w,l_j) = w^{1-\lambda}(w^{1-\gamma}) \]

where \( \gamma < 1 \). The parameter \( \lambda \) controls the level of taxation—higher values of \( \lambda \) imply lower average taxes. The parameter \( \gamma \) controls the progressivity of the tax code. When \( \gamma \) is positive, the average tax rate rises with income, so the tax system is progressive.

To illustrate the properties of the status-quo equilibrium in closed form, we assume that the utility function is given by

\[ u(c_j, l_j) + v(G) = \log(c_j) - \frac{\xi l_j^{1+\nu}}{1+\nu} + \chi \log(G). \]

These preferences, which are also used in ALES, KURNAZ and SLEET (2015) and HEATHCOTE et al. (2017), have two desirable properties: they are consistent with balanced growth and with the empirical evidence reviewed in CHETTY (2006).

For these preferences and the status-quo tax specification the equilibrium is easily computed. Worker optimality implies that hours worked are constant and depend on the preference parameters \( \xi \) and \( \nu \), and the progressivity parameter \( \gamma \).

\[ l_j = \left( \frac{1-\gamma}{\xi} \right)^{\frac{1}{1+\nu}} \equiv \ell. \]

Consumption of worker type \( j \) is equal to

\[ c_j = \lambda(w^\ell)^{1-\gamma}. \]

This property implies that the ratio of consumption of routine and non-routine workers is

\[ \frac{c_r}{c_n} = \left( \frac{w_r}{w_n} \right)^{1-\gamma} = \frac{\phi^{1-\gamma}}{\alpha A^{1/\alpha}(1-\alpha)^{1-\alpha}} \]

and that the equilibrium level of automation is

\[ m = 1 - \left[ \frac{\phi}{(1-\alpha)A} \right]^{1/\alpha} \frac{\pi_r}{\pi_n}. \]
We assume that government spending is a fraction $\chi$ of aggregate consumption. This assumption is natural since, given the form of the utility function, the optimal ratio of government spending to consumption is $\chi$. We also assume that tax progressivity, $\gamma$, is constant and that the government adjusts $\lambda$ to maintain budget balance. The resulting value of $\lambda$ is

$$\lambda = \frac{1}{1 + \chi \sum_{j=n,r} \pi_j w_j \ell \left( \frac{w_j \ell}{1 - \gamma} \right)}.$$  \hfill (23)

To investigate the impact of technical progress, we compute the equilibrium effects of a marginal increase in $\phi^{-1}$, corresponding to a fall in the robot production cost, $\phi$.

As robots become cheaper, pretax labor income rises for non-routine workers and falls for routine workers:

$$\frac{d \log(w_n \ell)}{d \log \phi^{-1}} = \frac{1 - \alpha}{\alpha}, \quad \text{and} \quad \frac{d \log(w_r \ell)}{d \log \phi^{-1}} = -1.$$  \hfill (24)

This divergence is associated with an increase in the number of tasks that are automated by replacing routine workers with robots:

$$\frac{d \log(1 - m)}{d \log \phi^{-1}} = -\frac{1}{\alpha}.$$  \hfill (25)

Higher pretax income inequality leads to higher consumption inequality:

$$\frac{d \log c_n / c_r}{d \log \phi^{-1}} = \frac{1 - \gamma}{\alpha}.$$  \hfill (26)

When income taxes are progressive ($\gamma > 0$), consumption inequality rises by less than pretax income inequality.

The impact of technical progress on individual consumption depends on the response of pretax income and also on how the parameter that controls the level of taxation, $\lambda$, adjusts. Interestingly, $\lambda$ rises as technical progress rises.

To further illustrate the properties of the model, we parameterize this model using the calibration of the dynamic model in section 5.
In Figure 1, we consider a sequence of static economies, in which the cost of producing robots falls according to $\phi_t = \tilde{\phi}e^{-g\phi_t}$ ($t = 1$ corresponds to 1987). As the cost of robots falls over time, the consumption of non-routine workers rises and the consumption of routine workers falls. The cost of robots converges to zero asymptotically, driving the consumption of routine workers towards zero.

In sum, our analysis suggests that under the current U.S. tax system a fall in automation costs will lead to massive income and welfare inequality.

3.2 Optimal taxation in the static model

It is useful to briefly consider the allocation that maximizes welfare subject only to technological constraints. Implementing this first-best allocation requires setting agent-specific lump-sum taxes.

We assume that the social welfare function is a weighted average of individual workers utilities. The weights on the social welfare function, $\omega_n$ and $\omega_r$ for non-
routine and routine agents, respectively, are normalized so that \( \pi_r \omega_r + \pi_n \omega_n = 1 \).

The planner’s problem is to choose allocations to maximize social welfare,

\[
W \equiv \pi_r \omega_r \left[ u(c_r, l_r) + v(G) \right] + \pi_n \omega_n \left[ u(c_n, l_n) + v(G) \right].
\] (27)

subject only to the economy’s resource constraint.

The first-best allocation always features production efficiency. This property implies that the marginal productivity of robots equals their marginal cost, \( \phi \), so the robot tax is zero. As we have seen, without taxes on robots a fall in \( \phi \) leads to an increase in pretax wage inequality. However, since the first best features unrestricted taxes/transfers, it is always possible to redistribute income without creating distortions. As a result, pretax wage inequality does not constrain redistribution, and both workers benefit from technical progress.

In general, the first-best solution cannot be implemented if the planner cannot discriminate between worker types. To see the intuition for this result, consider the case in which \( \omega_n = \omega_r \) and the workers’ utility function is separable in consumption and leisure. In this case, routine and non-routine workers have the same level of consumption but non-routine workers work longer hours than routine workers. As a consequence, non-routine workers would have an incentive to act as routine to obtain a more generous consumption and leisure bundle.

In what follows, we consider a restricted planning problem. We show that if the planner cannot discriminate across worker types, then pretax wage inequality becomes relevant in order to determine how much redistribution can be done.

**Mirrleesian optimal taxation** In this section, we characterize the non-linear income tax schedule that maximizes social welfare when the planner observes a worker’s total income but does not observe the worker’s type or labor supply, as in Mirrlees (1971).
We focus on the case where the level of automation is interior, \(m > 0\). We also assume that \(\phi \leq \alpha^a(1 - \alpha)^{1-a}A\), so that if \(\tau^x \leq 0\) non-routine workers earn a higher wage than the routine, \(w_n \geq w_r\) (see equations (14) and (15)).

The Mirrleesian planning problem is to choose the allocations \(\{c_j, l_j\}_{j=n,r,G}\) and the robot tax \(\tau^x\) to maximize social welfare, (27), subject to the resource constraint

\[
\pi_r c_r + \pi_n c_n + G \leq \pi_n w_n l_n \frac{\tau^x + \alpha}{\alpha(1 + \tau^x)} + \pi_r w_r l_r \frac{1 + \tau^x}{1 + \tau^x}.
\]

and two incentive constraints (IC)

\[
u(c_n, l_n) \geq u \left(c_r, \frac{w_r}{w_n} l_r \right),
\]

\[
u(c_r, l_r) \geq u \left(c_n, \frac{w_n}{w_r} l_n \right).
\]

The wages of the two types of workers are given by equations (14) and (15). The conditions (28), (29), and (30) are necessary and sufficient to describe a competitive equilibrium. We discuss these properties in the appendix.

In Mirrlees (1971)’s model, the productivities of the different agents are exogenous. Atkinson and Stiglitz (1976) show that production efficiency is optimal in that environment. Our model features instead endogenous productivities that depend on \(\tau^x\). This property turns out to be central to the question we are interested in studying: whether it is optimal to tax robot use, distorting production, in order to redistribute income from non-routine to routine workers. Based on the work of Stiglitz (1982) and Naito (1999), who first considered the impact of endogenous productivities in the design of the optimal tax system, we should expect production efficiency to no longer be optimal. That is indeed the case in our model. As long as automation is interior, robot taxes are positive in our model, as stated in proposition 1.

\[13\] When \(m = 0\), this simple model is a special case of the one considered in Stiglitz (1982).
The expression for net output on the right-hand side of equation (28) can be written as
\[
\frac{\tau^x + \alpha}{\alpha (1 + \tau^x)^{1/\alpha}} A^{1/\alpha} (1 - \alpha)^{1-x} \pi_n l_n + \phi \pi_n l_r.
\]
The term \((\tau^x + \alpha) / \left[\alpha (1 + \tau^x)\right]^{1/\alpha}\) is equal to one for \(\tau^x = 0\) and strictly less than one for \(\tau^x \neq 0\). This term is a measure of the production inefficiency created by the robot tax.

Proposition 1 shows that, when automation is incomplete, the planner is willing to bear a resource cost, in terms of production inefficiency, to loosen the incentive constraint. In this proposition, we characterize the optimal allocation under the assumption that the planner wants to redistribute to routine workers to an extent such that the incentive constraint of the non-routine worker binds and the incentive constraint of the routine worker is slack. This approach is standard in the literature.

**Proposition 1.** Suppose the optimal allocation is such that the incentive constraint binds for non-routine workers and does not bind for routine workers. Then, if automation is incomplete \((m < 1)\), optimal robot taxes are strictly positive \((\tau^x > 0)\).

This proposition is proved in the appendix. The intuition for this result is that starting from any robot tax that is less than or equal to zero, \(\tau^x \leq 0\), there are welfare gains from increasing this tax rate. First, suppose that the tax on robots was strictly negative, \(\tau^x < 0\). In this case, a marginal increase in \(\tau^x\) has two benefits. First, it strictly increases output and hence the amount of goods available for consumption for given levels of the labor supplies. Second, it reduces the non-routine wage premium, \(w_n/w_r\), and makes the non-routine worker less inclined to mimic the routine worker. This property can be easily seen from the incentive constraint of the non-routine worker, (29).

Suppose instead that the robot tax is zero, \(\tau^x = 0\). Since, for a given level of the labor supplies, the value of \(\tau^x\) maximizes output, a marginal increase in that tax produces only second-order output losses. On the other hand, increasing \(\tau^x\) generates
a first-order gain from loosening the incentive constraint. Therefore, starting from $\tau^x = 0$, the planner can always improve welfare with a marginal increase in $\tau^x$.

Robot taxes are optimal only when automation is incomplete ($m < 1$), so that routine workers are employed in production ($l_r > 0$). When full automation is optimal ($m = 1$ and $l_r = 0$) there are no informational gains from taxing robots. Since the robot tax distorts production and does not help loosen the incentive constraint of the non-routine agent, the optimal value of $\tau^x$ is zero (see the appendix for a proof).

4 A dynamic model

In this section, we study the optimal tax policy in a model with endogenous occupation choice. We consider an overlapping-generations model where workers choose their occupation when they enter the workforce, work in the following periods and then retire.

For computational reasons, we assume that each period represents a decade. Agents live for six periods, working in the first four and retiring in the last two. We assume that robots produced at time $t$ can be immediately used in production, so there is no time to build, and robots depreciate fully within the period.\(^{14}\)

As in the static model, technical change reduces the cost of producing robots over time. Because robots are better substitutes for routine than for non-routine workers, technical change is biased towards non-routine skills and increases the non-routine wage premium. This effect is analogous to the impact on the skill premium of technical change with capital-skill complementarity discussed in Kruse, Ohanian, Rios-Rull and Violante (2000).

\(^{14}\)The standard modeling of capital accumulation embodies a one-period time to build: capital goods used in production at time $t$ are produced at time $t - 1$. This formulation would introduce a time-to-build period of ten years in robot production, which is unreasonable.
Workers and preferences  Time is discrete with an infinite horizon \( t = 1, 2, ... \). For simplicity, we assume that each generation is composed of a unit measure of workers. Workers live for \( L \) periods, and work for \( L_w \leq L \) periods. We use \( a \in \{0, ..., L - 1\} \) to denote a worker’s age: \( a = 0 \) denotes the first period of life and \( a = L - 1 \) the final period.

Workers born before the initial date, \( t = 1 \), enter the economy with age \( a \geq 1 \). The initial older generations cannot acquire new skills. A share \( \pi_r,1-a \) of these workers are routine and \( \pi_n,1-a \) are non-routine. We denote the consumption and labor supply of those workers in occupation \( j \) and age \( a \) at time \( t \) by \( c_{a,j,t} \) and \( l_{a,j,t} \), respectively. Workers value streams of consumption, government spending, and leisure according to the utility function

\[
U_{j,1-a} \equiv \sum_{t=1}^{L-a} \beta^{t-1} \left[ u \left( c_{a+(t-1),j,t} \right) + v(G_t) \right] - \sum_{t=1}^{L_w-a} \beta^{t-1} \psi \left( l_{a+(t-1),j,t} \right),
\]

where \( U_{j,1-a} \) denotes their utility level and \( \beta \) is the subjective discount factor. We assume that the utility function is separable in consumption and labor and satisfies the standard assumptions about monotonicity, concavity, and Inada conditions.

Workers born in period \( t \geq 1 \), have heterogeneous utility costs of skill acquisition, \( \theta \in \Theta \). We assume that these costs follow a distribution \( H \) with continuous p.d.f. \( h \). We denote by \( c_{\theta,j,t}^a \) the consumption of a worker with skill cost \( \theta \) and age \( a \) at time \( t \), and by \( l_{\theta,j,t}^a \) their labor supply. The lifetime utility of a worker born in period \( t \), without including skill acquisition costs, is:

\[
U_{\theta,t} \equiv \sum_{a=0}^{L-1} \beta^a \left[ u \left( c_{\theta,t+a}^a \right) + v(G_{t+a}) \right] - \sum_{a=0}^{L_w-a} \beta^a \psi \left( l_{\theta,t+a}^a \right).
\]

This worker’s overall utility is equal to lifetime utility net of the costs of skill acquisition, \( U_{\theta,t} - \theta s_{\theta,t} \). The indicator function \( s_{\theta,t} \in \{0, 1\} \) denotes the worker’s skill choice, where \( s_{\theta,t} = 0 \) denotes routine skills and \( s_{\theta,t} = 1 \) denotes non-routine skills.

Workers with positive values of \( \theta \) face a positive cost of acquiring non-routine skills, which means that, all else equal, they would prefer to acquire routine skills.
Workers with negative values of \( \theta \) prefer, all else equal, to acquire non-routine skills. We denote by \( \Theta_{r,t} \) and \( \Theta_{n,t} \) the subsets of \( \Theta \) which correspond to the choice of routine and non-routine occupations, respectively, i.e., \( \Theta_{n,t} \equiv \{ \theta : s_t(\theta) = 1 \} \) and \( \Theta_{r,t} \equiv \Theta - \Theta_{n,t} \).

Throughout, we use \( \pi_{n,t} \equiv \int_{\Theta_{n,t}} h(\theta) d\theta \) to denote the share of non-routine workers in the newborn population at time \( t \), and \( \pi_{r,t} \equiv 1 - \pi_{n,t} \) to denote the share of routine workers in the newborn population at time \( t \).

**Firms and technology**  
Robots and final output are produced by competitive firms using the same production technology as in the static model. Robots cost \( \phi_t \) units of output to produce at time \( t \). Final output is produced according to (4), so the elasticity of substitution between total tasks and non-routine labor is equal to one. This property is important in order to ensure the existence of a balanced-growth path which is reached asymptotically.

A representative final-goods firm maximizes per-period profits, by choosing how much to produce, how much labor to hire, and how many robots to buy. The firm hires non-routine labor at the wage rate \( w_{n,t} \), routine labor at the wage rate \( w_{r,t} \), and pays the robot cost gross of taxes, \( (1 + \tau^{\ell})\phi_t \). The first-order conditions for this profit maximization problem for each period \( t \) are the analog of the first-order conditions (5)-(7).

Without loss of generality, suppose that tasks are ordered so that \( \kappa_i / \ell_i \) is weakly decreasing in \( i \in [0, 1] \). This property implies that routine workers are relatively more efficient in tasks indexed by higher values of \( i \). Given this assumption, the firm uses robots in the first \( m_t \) tasks and routine workers in the final \( 1 - m_t \) tasks. The optimal allocation of routine workers and robots to each of those tasks is described by the same first-order conditions as in the static model. These conditions imply:

\[
x_{i,t} = \frac{\kappa_i^{\rho-1}}{\int_0^{m_t} \kappa_j^{\rho-1} \, dj} X_t, \quad i \in [0, m_t] \quad \text{and} \quad n_{i,t} = \frac{\ell_i^{\rho-1}}{\int_{m_t}^1 \ell_j^{\rho-1} \, dj} N_{r,t}, \quad i \in (m_t, 1].
\]
Following Acemoglu and Restrepo (forthcoming, 2019), we replace these expressions in the production function and obtain:

\[ Y_t = A \left[ \left( \int_0^{m_t} \kappa_i^{\rho-1} di \right)^{\frac{1}{\rho}} X_t^{\rho-1} + \left( \int_{m_t}^1 \ell_i^{\rho-1} di \right)^{\frac{1}{\rho}} N_{r,t}^{\rho-1} \right]^{\frac{\rho}{\rho-1}(1-\alpha)} N_{n,t}^\alpha. \]

The firm’s optimal choice of the level of automation implies:

\[ \frac{X_t}{N_{r,t}} = \frac{\int_0^{m_t} \kappa_i^{\rho-1} di \ell_i^{\rho}}{\int_{m_t}^1 \ell_i^{\rho-1} di \kappa_i^{\rho m_i}}. \]

At this level of generality, we cannot solve for \( m_t \) in closed form. As in Chen (2019), we make the analysis more tractable by introducing the following assumption:

**Assumption 1.** \( \kappa_i = \varsigma_i \epsilon^{\frac{\epsilon-1}{\epsilon}} \) and \( \ell_i = \varsigma_i (1-i) \epsilon^{\frac{\epsilon-1}{\epsilon}} \) where \( \varsigma = \left[ 1 + \frac{(\epsilon-1)(\rho-1)}{\epsilon} \right]^{\frac{1}{\rho-1}} \) and \( (1-\epsilon)(\rho-1)/\epsilon < 1. \)

Under this assumption, the optimal value of \( m_t \) is given by

\[ m_t = \frac{X_t^\epsilon}{X_t^\epsilon + N_{r,t}^\epsilon}. \]

The routine tasks aggregator becomes a CES aggregator of total robots and routine labor, where \( \epsilon \leq 1. \) The elasticity of substitution between robots and routine workers is given by \( 1/(1-\epsilon). \) The production function becomes:

\[ Y_t = A \left( X_t^\epsilon + N_{r,t}^\epsilon \right)^{\frac{1-\alpha}{\epsilon}} N_{n,t}^\alpha. \]

We write this production function as \( F(X_t, N_{r,t}, N_{n,t}) \) and denote its partial derivatives at time \( t \) as \( F_{X,t} \) and \( F_{j,t} \) for \( j = n, r. \) Wages are equal to the worker’s marginal productivity

\[ w_{j,t} = F_{j,t}. \]
We want to focus on environments in which robots have a higher degree of complementarity with non-routine workers than with routine workers. For this reason, we assume that \( \varepsilon > 0 \) so that routine workers and robots are substitutes. This assumption implies that the elasticity of the non-routine wage premium with respect to robot use is
\[
E_t \equiv \frac{d \log \left( \frac{F_{n,t}}{F_{r,t}} \right)}{d \log X_t} = \varepsilon m_t \geq 0.
\]

To make the model consistent with the life-cycle profile of labor earnings, we assume that workers of age \( a \) supply \( e_a \) units of labor in efficiency units per hour worked. Total labor supply for occupation \( j = n, r \) at time \( t \) must satisfy the market-clearing condition:
\[
N_{j,t} = \begin{cases} 
\sum_{\theta=0}^{L_w-1} \int_{\Omega_{j,t-a}} e_a l_{a,t}^j h(\theta) d\theta + \sum_{a=1}^{L_w-1} \pi_{j,t-a} e_a l_{a,t}^j, & \text{if } t < L_w \\
\sum_{\theta=0}^{L_w-1} \int_{\Omega_{j,t-a}} e_a l_{a,t}^j h(\theta) d\theta, & \text{if } t \geq L_w.
\end{cases}
\] (35)

Aggregated consumption at time \( t \), \( C_t \), is given by:
\[
C_t = \begin{cases} 
\sum_{\theta=0}^{L_w-1} \int_{\Omega} e_\theta l_{\theta,t} h(\theta) d\theta + \sum_{j=n,r} \sum_{a=1}^{L_w-1} \pi_{j,t-a} e_a l_{a,t}^j, & \text{if } t < L_w \\
\sum_{\theta=0}^{L_w-1} \int_{\Omega} e_\theta l_{\theta,t} h(\theta) d\theta, & \text{if } t \geq L_w.
\end{cases}
\] (36)

Using these definitions, the resource constraint in period \( t \) can be written as
\[
C_t + G_t \leq F(X_t, N_{r,t}, N_{n,t}) - \phi_t X_t, \quad (37)
\]

We define net output \( NY_t = Y_t - \phi_t X_t \).

### 4.1 First-best allocation

We assume that the planner assigns Pareto weights \( \omega_{j,1-a} \) to workers born before the initial period, and \( \beta^t \omega_{\theta,t} \) to agents of type \((\theta, t)\). Importantly, we need to assume that the sum of the welfare weights is finite:
\[
\sum_{j=n,r} \sum_{a=1}^{L-1} \pi_{j,1-a} \omega_{j,1-a} + \sum_{t=1}^{\infty} \int_{\Theta} \beta^{t-1} \omega_{\theta,t} h(\theta) d\theta < \infty.
\]

24
To ensure that the first best has a well defined steady-state allocation, we assume that the *current-value* weights converge in the long run, i.e., for all $\theta$, $\omega_{\theta,t} \to \omega_\theta \geq 0$ as $t \to \infty$. The planner’s objective function is

$$W \equiv \sum_{a=1}^{L-1} \sum_{j=n,r} \pi_{j,1-a} \omega_{j,1-a} U_{j,1-a} + \sum_{t=1}^{\infty} \int_\Theta \beta^{t-1} \omega_{\theta,t} h(\theta) \tilde{U}_{\theta,t} d\theta.$$  

(38)

The first-best allocation maximizes this welfare function subject to the resource constraints, (37). The solution to this problem implies the following efficiency conditions:

$$\frac{\psi'(l_{\theta,t}^a)}{u'(c_{\theta,t}^a)} = e_a F_{s_{\theta,t-a}}(t),$$

$$\omega_{\theta,t-a} u'(c_{\theta,t}^a) = \omega_{\theta,t-a} u'(c_{\theta,t}^{a'}),$$

for all $\theta, \theta', a, a'$ and $t$, and

$$F_X(t) = \phi_t.$$

### 4.2 Mirrleesian taxation

As in the dynamic Mirrleesian taxation literature, we characterize the second-best problem for a planner who can design allocations which are functions of observable histories of income and consumption, but not of each worker’s type, wage, or skill choice. We assume that the planner can tax the different generations differently. This assumption is a common in the optimal-taxation literature.

We consider a direct revelation mechanism in which the planner elicits information on the worker’s type and assigns them a profile of consumption, labor supply, and a skill choice. In line with \textsc{Scheuer (2014)}, we can write the implementability constraints are as follows.

The first incentive constraint is the same as in the static model. For the workers which are born before the initial date, and have $a < L_w$ at $t = 1$, this is the only
relevant constraint:\footnote{There is no incentive problem for those agents that no longer work.}
\begin{align}
    U_{n,1-a} & \geq U_{r,1-a} + \sum_{t=1}^{L_w-a} \beta^{t-1} \left[ \psi \left( I_{r,t}^a + (t-1) \right) - \psi \left( \frac{F_{r,t}}{F_{n,t}} I_{r,t}^a + (t-1) \right) \right], \\
    U_{r,1-a} & \geq U_{n,1-a} + \sum_{t=1}^{L_w-a} \beta^{t-1} \left[ \psi \left( I_{r,t}^a + (t-1) \right) - \psi \left( \frac{F_{n,t}}{F_{r,t}} I_{r,t}^a + (t-1) \right) \right].
\end{align}

for \(a = 1, \ldots, L_w - 1\). For the workers born after the initial date, this constraint is
\begin{align}
    U_{\theta,t} & \geq U_{\theta',t} + \sum_{a=0}^{L_w-1} \beta^{t-1} \left[ \psi \left( I_{\theta',t}^{a + (t-1)} \right) - \psi \left( \frac{F_{\theta',t}}{F_{\theta,t}} I_{\theta',t}^{a + (t-1)} \right) \right],
\end{align}
for all \(\theta, \theta' \in \Theta\) and \(t \geq 1\). This \emph{intensive-margin incentive constraint} guarantees that
the worker chooses the assigned allocation, given their occupation choice. The second condition is the incentive constraint for the choice of occupation of
an individual of type \(\theta\):
\begin{align}
    U_{\theta,t} - \theta s_{\theta,t} & \geq U_{\theta',t} - \theta s_{\theta',t},
\end{align}
for all \(\theta, \theta' \in \Theta\) and \(t = 1, 2, 3, \ldots\). This \emph{extensive-margin incentive constraint} ensures that
the worker chooses the assigned occupation.\footnote{These constraints do not explicitly take into account the possibility that agent \(\theta\) might choose an
allocation that corresponds to an occupational choice different from \(s_{\theta',t}\). However, those additional
constraints are redundant.} The planning problem is to maximize
\[(38)\] subject to these incentive constraints and the resource constraints, \((37)\).

As in \textsc{Scheuer} \textit{et al.} (2014), we now state two results which allow us to simplify the
analysis.\footnote{The proofs can be found in the appendix.}

\textbf{Lemma 1.} An allocation satisfies the extensive margin incentive constraints if and only if
for all \(t\) there exists \(U_{n,t}, U_{r,t} \in \mathbb{R}\) and \(\theta^* = U_{n,t} - U_{r,t}\) such that:
\begin{enumerate}
    \item If \(\theta < \theta^*_t\), then \(s_{\theta,t} = 1\) and \(U_{\theta,t} = U_{n,t}\);
    \item If \(\theta > \theta^*_t\), then \(s_{\theta,t} = 0\) and \(U_{\theta,t} = U_{r,t}\).
\end{enumerate}
This lemma allows us to simplify the incentive constraints. For an allocation to be incentive compatible, all workers that choose the same skill should have the same utility gross of skill acquisition costs. This property allows us to express the incentive constraints as a cut-off rule: workers with $\theta < \theta^*$ acquire non-routine skills, while those with high $\theta > \theta^*$ acquire routine skills.

The next lemma, allows us to further simplify the problem. This lemma shows that all workers who have the same skills should have the same allocation in terms of consumption and labor.

**Lemma 2.** At the optimum, if $s_{\theta,t} = s_{\theta',t}$ then these two workers have the same consumption at each age $c_{\theta,t+a}^a = c_{\theta',t+a}^a$, for $a = 0, ..., L - 1$, and the same labor supply $l_{\theta,t+a}^a = l_{\theta',t+a}^a$, for $a = 0, ..., L_w - 1$.

To find the allocations for routine and non-routine workers it is useful to define:

$$U_{j,t} \equiv \sum_{a=0}^{L-1} \beta^a \left[ u(c_{j,t+a}^a) + v(G_{t+a}) \right] - \sum_{a=0}^{L_w-1} \beta^a \psi(l_{j,t+a}^a),$$

for $j = n, r$. The number of incentive constraints can be simplified to just two per generation born before time $t = 1$, (40) and (39), and three constraints per generation born after $t = 1$,

$$\theta^* = U_{n,t} - U_{r,t}, \quad (43)$$

and

$$U_{n,t} \geq U_{r,t} + \sum_{a=0}^{L_w-1} \beta^a \left[ \psi(l_{r,t+a}^a) - \psi\left(\frac{F_{r,t+a}l_{r,t+a}^a}{F_{n,t+a}l_{n,t+a}^a}\right) \right], \quad (44)$$

$$U_{r,t} \geq U_{n,t} + \sum_{a=0}^{L_w-1} \beta^{t-1} \left[ \psi(l_{r,t+a}^a) - \psi\left(\frac{F_{r,t+a}l_{r,t+a}^a}{F_{n,t+a}l_{n,t+a}^a}\right) \right]. \quad (45)$$

The next proposition states results analogous to those we obtained for the static model. As long as automation is incomplete and at least one intensive-margin incentive constraint binds, (39) or (44), it is optimal to tax robots in a given period.
Proposition 2. At the optimal plan, suppose that at time $t$ there is an age $a$, such that: (i) the intensive-margin constraint for non-routine aged $a$ at time $t$ is binding and (ii) $l^a_{r,t} > 0$; and no intensive-margin constraint of routine workers working at time $t$ is binding. Then, robot usage should be distorted $F_X(t) < \phi_t$, that is, robots should be taxed.

Since this model features endogenous skill acquisition, the intensive margin incentive constraint of non-routine workers might not bind even when the government wants to redistribute income towards routine workers. This is because the government can redistribute income in two ways. The first, which we call the direct redistribution mechanism is to redistribute income from non-routine to routine workers. This mechanism is the one used in our static model. But in a model with endogenous skill choice, this mechanism reduces the incentive for workers to acquire non-routine skills.

The second, which we call the indirect redistribution mechanism, involves little income redistribution in order to provide an incentive for workers to acquire non-routine skills. When this mechanism is the most relevant, the intensive-margin incentive constraint no longer binds. Because robot taxes are only desirable insofar as they help provide incentives along the intensive margin, then, if the government redistributes indirectly, robot taxes should be zero. Which mechanism turns out to be optimal is a quantitative question.

Asymptotic balanced growth We assume that the cost of robots declines geometrically over time as a result of exogenous technical progress, $\phi_t = \tilde{\phi} e^{-g^t}$. In addition, we assume that $u(\cdot)$ and $v(\cdot)$ are logarithmic functions so that preferences are consistent with balanced growth.

Assumption 2 (Preferences). The utility function takes the form $u(c) = \log(c)$ and $v(G) = \chi \log(G)$, with $\chi > 0$.

These preferences have been used in different public finance applications, espe-
cially the ones featuring technical change, see, for example, ALES et al. (2015). Recall that these preferences are also compatible with the empirical evidence reviewed in CHETTY (2006).

The variables in the model can be normalized to remove trends (see appendix A.2.4). We call the version of our model expressed in terms of these normalized variables the normalized economy. We say that the economy is in a balanced-growth path if the allocations of the normalized economy are constant over time, that is, the normalized economy is in a steady state.

In dynamic optimal taxation problems, the steady-state allocations generally depend on initial conditions, see for example CHAMLEY (1986) or SLAVÍK and YAZICI (2014). This dependence requires solving for the balanced-growth path and transition jointly, which is often challenging from a computational standpoint. In our model the steady state of the normalized economy is independent of initial conditions. The reason for this result is that in our overlapping-generations structure workers have finite horizons and the government can treat different generations differently.

We show in appendix A.2.5 that if aggregate consumption, government spending, aggregate labor supply, robot use, and the cutoff \( \theta_t^* \) converge to an interior balanced-growth path, then all other variables including individual allocations and Lagrange multipliers also converge to constant values. In the appendix, we show the necessary and sufficient conditions to compute this balanced-growth path.

**Proposition 3.** Suppose that the optimal plan is such that the allocations converge to a balanced-growth path with interior automation. Then, the optimal tax on robots converges asymptotically to zero.

This proposition is true irrespective of the distribution of skill-acquisition costs. As a result, it holds even if costs are arbitrarily high, that is, in an economy with exogenous skills.
The fact that the optimal robot tax converges asymptotically to zero is reminiscent of the celebrated Chamley-Judd result on zero long-run capital taxation. This result stands in contrast with the optimal tax scheme in SLAVÍK and YAZICI (2014). These authors consider optimal Mirrleesian taxation in an infinite-horizon model with low- and high-skill workers and capital-skill complementarity. They find that in this setting optimal asymptotic production distortions are high.

SLAVÍK and YAZICI (2014) abstract from technical progress. In the presence of technical progress, the asymptotic balanced-growth path would be such that the workers for whom wages fall no longer supply any labor. As a result, there is no reason to affect pretax wages to provide intensive-margin incentives and thus production efficiency is optimal. In the same way that in our model robot taxes converge to zero, capital taxes would also converge to zero in a version of the SLAVÍK and YAZICI (2014) with technical progress.

5 Quantitative analysis

In this section, we describe our calibration and solve the planning problem in order to quantify the effects of advances in automation on optimal tax policy.

5.1 Parameter calibration

We calibrate the parameters so that the status-quo economy matches salient features of the U.S. economy for the period 1987-2017. Table 1 summarizes the calibrated parameters.

Our calibration targets the non-routine wage premium and the occupation shares of each skill type. We obtain time series for these variables using data from Current Population Survey March Annual Supplement obtained from FLOOD et al. (2018)’s IPUMS.
The utility function is assumed to be isoelastic in consumption, labor, and government spending

\[ u(c) = \log c, \quad \psi(l) = \zeta \frac{l^{1+\nu}}{1+\nu}, \quad v(G) = \chi \log G. \quad (46) \]

This utility specification is consistent with balanced growth. The cross-sectional distribution of \( \theta, h(\theta) \), follows a logistic distribution with location parameter \( \mu \), and scale parameter \( \sigma \).  

In the status-quo, conditional on a given skill choice, all workers solve the same problem. Workers of the same occupation choose the same consumption, labor supply, and savings and obtain the same utility,

\[ U_{\theta,t} = \begin{cases} U_{n,t} & \text{if } s_{\theta,t} = 1 \\ U_{r,t} & \text{if } s_{\theta,t} = 0, \end{cases} \quad (47) \]

for the equilibrium levels of \( U_{j,t} \). As a result, the skill choice can be described by a threshold rule \( \theta^*_t = U_{n,t} - U_{r,t} \), such that all newborns at time \( t \) with \( \theta < \theta^*_t \) choose non-routine skills, and those with \( \theta > \theta^*_t \) choose routine skills.

The budget constraint for workers at time \( t \), aged \( a \), in a particular occupation is given by

\[ c_{a,j,t} + \frac{b_{a,j,t}}{R_t} = b_{a-1,j,t-1} + w_{j,t}e_{a}l_{a,j,t} - T_t(w_{j,t}e_{a}l_{a,j,t}), \quad \text{for } a = 0, \ldots, L_w - 1, \quad (48) \]

\[ c_{a,j,t} + \frac{b_{a,j,t}}{R_t} = b_{a-1,j,t-1}, \quad \text{for } a = L_w, \ldots, L - 1, \quad (49) \]

where initial wealth holdings are zero \( b_{a-1,j,t-1} = 0 \), and the final wealth holdings are also zero, \( b_{a,j,t-1} = 0 \). Here, \( R_t \) denotes the gross real interest rate between \( t \) and \( t + 1 \). The taxation of labor earnings is the same as in Heathcote et al. (2017), which means that \( T(y) = y - \lambda_t y^{1-\gamma} \).

---

\(^{18}\)This assumption is equivalent to assuming that the worker has occupation-specific utility costs of acquiring skills, \( \theta_n \) and \( \theta_r \), and that these costs follow a Gumbel distribution. This distributional assumption has been widely used in the literature on discrete choice following McFadden (1974), see for example Johnson and Keane (2013) and Roys and Taber (2019).
The government’s flow constraints is given by

\[ G_t + B_{t-1} = \sum_{a=0}^{L_w-1} \sum_{j=n_f} \pi_{j,t-a} T_t \left( w_{j,t} e_{a, j,t} \right) + \frac{B_t}{R_t}. \]  

(50)

In our calibration exercises, we set the ratios of government spending to consumption, \( G_t / C_t \), and assets to consumption, \( B_t / C_t \), from the data, and let \( \lambda_t \) adjust so that the government budget constraint is satisfied.

We now describe how the remaining parameters are calibrated.

**Externally calibrated parameters** We assume that a time period corresponds to ten years. Workers live for six periods and work for four of these, that is, \( L = 6 \) and \( L_w = 4 \). Following Chetty et al. (2011), we set the Frisch elasticity to 0.75, \( \nu = 1 / 0.75 \). We calibrate \( e_a \) to match the life-cycle earnings profile in Guvenen et al. (2015). On the production side, we normalize \( A = 1 \).

When utility functions take the form (46), the optimal ratio of government spending to private consumption is equal to \( \chi \). We set the value of \( \chi \) to 0.19 to match the

</table>
average ratio of government spending to consumption in the data.

In the status-quo equilibrium, the tax on robots is zero, \( \tau^r_t = 0 \). We use the method in Ferriere and Navarro (2014) to calibrate \( \gamma \) using NBER TAXSIM data, and find \( \gamma = 0.18 \). This value is in line with the estimates in Heathcote et al. (2017). We use World Bank data to compute the ratio of government spending to private consumption, \( G_t / C_t \), and the ratio of government bonds to private consumption, \( B_t / C_t \). We take 10-year averages of these ratios, from 1988–97, 1998–2007, and 2008–17. We assume that from 2018 onward, this ratio remains constant at its 2017 value. These ratios are displayed in Figure 2. We feed the values of \( G_t \) and \( B_t \) exogenously so as to be consistent with these ratios and adjust the level parameter in the tax function, \( \lambda_t \), to satisfy the government budget constraint, (50).

We then proceed with our calibration in two steps: we first find a steady state for the normalized economy with fixed occupations and zero automation for 1987. We use this steady state to calibrate the subjective discount factor, \( \beta \), the labor disutility parameter, \( \zeta \), and the share of non-routine workers in production, \( \alpha \). Next, we compute a perfect foresight transition to the new balanced growth path, and use the data on the non-routine wage premium and the occupation shares between 1987–2017 to calibrate the cost of robots, \( \tilde{\phi} \), the rate of technical progress in robot production, \( g_\phi \), the elasticity of routine workers and robots, \( 1/(1 - \varepsilon) \), and the parameters of the distribution of skill-acquisition costs, \( \mu \) and \( \sigma \).

**Pre-automation steady-state equilibrium**  Our first step is to calibrate the steady state before automation so as to match the ratio of government spending to private-consumption and the government debt to private consumption ratios for 1987. We also calibrate the shares of routine and non-routine workers to match their 1987 shares: \( \pi_n = 0.44 \) and \( \pi_r = 0.56 \). In the pre-automation steady state these occupational shares are constant across generations.

Following Gourinchas and Parker (2002), we impose \( \beta R = 1 \). We choose the
labor disutility parameter, $\zeta$, so that on average the labor supply is equal to $1/3$. Finally, we calibrate $\alpha$ so that the non-routine wage premium is $w_n/w_r = 1.19$. This calibration leads to $\beta = 0.39$, $\zeta = 29.57$, and $\alpha = 0.48$.

![Figure 3: Calibration fit](image)

**Transitional dynamics and steady state** We solve for the perfect-foresight transition between the initial and the final steady state of the normalized economy.

In the asymptotic final steady state there is full automation. Labor hours and consumption are zero for routine workers so all workers choose non-routine occupations. We first solve numerically for the asymptotic steady state, and then solve for the transitional dynamics.\(^{19}\)

We choose the technological parameters $\bar{\phi}$, $g_{\phi}$, and $\epsilon$, plus the skill-acquisition parameters $\mu$ and $\sigma$ to match the time series of observed occupation shares and the non-routine wage premium. Using a least-squares procedure, we find $\bar{\phi} = 0.48$.

---

\(^{19}\)Our numerical method exploits some of the ideas proposed by Auclert, Bardóczy, Rognlie and Straub (2019). We describe the full set of equilibrium conditions and the numerical method in the appendix.

35
$g_\phi = 0.02$, and $\varepsilon = 1$, plus $\mu = 0.32$, and $\sigma = 0.23$. Figure 3 shows that our model fits quite well the ten year average trends in both the occupation shares and the non-routine wage premium.

Figures 4 and 5 plot prices and allocations for the status-quo economy. The first panel shows the declining cost of robots. The second panel shows that as these costs fall, automation rises. The third panel shows that net output rises. However, the benefits of this rise are very unequally distributed. Panel 4, shows that wages fall for those who are in routine occupations and rise for those in non-routine occupations.

Panels 5 and 6 show the cross-sectional average of labor supply and consumption for routine and non-routine workers computed as follows: $\bar{c}_{j,t} \equiv L^{-1} \sum_{a=0}^{L-1} \pi_{j,t-a} c^a_{j,t}$ and $\bar{l}_{j,t} \equiv L^{-1} \sum_{a=0}^{L-1} \pi_{j,t-a} l^a_{j,t}$. Because our model has preferences consistent with balanced growth, labor supply is fairly constant and close to 0.33. Panel 6 shows that consumption rises for non-routine workers and falls for routine workers.
As routine wages decline, more agents decide to become non-routine workers (see Figure 5). However, the occupational shares in the labor force, \( \pi_{j,t} \equiv L_{w}^{-1} \sum_{a=0}^{w-1} \pi_{j,t-a} \), respond sluggishly. This inertia reflects the inability of older generations to re-optimize their skill choices.

\[ \pi_{j,t} \equiv L_{w}^{-1} \sum_{a=0}^{w-1} \pi_{j,t-a} \]

Figure 5: Status-quo equilibrium B

5.2 Mirrleesian optimal taxation

Figures 6 and 7 display the optimal Mirrleesian allocation. Compared to the status-quo, the level of automation is initially lower, but rises rapidly. This property reflects the presence of robot taxes in the initial periods of the Mirrleesian solution.

Robot taxes are 8.5 percent between 1988–1997, 3.1 percent between 1998–2007, and 0.8 percent in the subsequent decade. The wage compression associated with these robot taxes loosens the incentive constraint of non-routine workers, which allows the government to redistribute more income from non-routine to routine work-
ers in the initial older generations, i.e., those with $a \geq 1$ at $t = 1$.

After these initial periods, the tax on robots falls permanently to zero. This fall reflects the fast rise in automation combined with a sharp rise in the percentage of workers who are non-routine. Compared to the status-quo economy, the Mirrleesian optimal plan induces many more workers to choose non-routine skills. Table 2 compares the composition of the labor force in the status-quo economy and the Mirrleesian optimal plan for the initial periods. It shows the share of workers who become non-routine workers in the newborn population, $\pi_{n,t}$, and the share of workers who are non-routine in the labor force, $\bar{\pi}_{n,t}$. 

Figure 6: Mirrleesian optimal taxation A
We can see that the share of non-routine is 13 percent higher in the Mirrleesian optimal plan than in the status-quo economy. This higher share reflects the proclivity of new generations for non-routine occupations. The model is consistent with Adão et al. (2018)’s finding of a weak response of old generations and a strong response of new generations to changes in wages across occupations. Redistribution through occupation choice, which we call the indirect redistribution mechanism, plays an
important role in these results. The planner designs allocations with little direct redistribution between worker types to that a higher share of workers in the new generations acquires non-routine skills. Consequently, the intensive margin incentive constraint no longer binds. Because robot taxes should be used only insofar as they help loosening the intensive-margin incentive constraint, robot taxes fall to zero.

Table 2 also shows that, despite large changes in the composition of the newborn population, the composition of the labor force changes slowly. This inertia reflects the inability of older workers to change occupations. Despite large differences in the composition of the newborn population, the share of non-routine workers in the labor force in the period 1988–1997 is only 4 percentage points higher in the Mirrleesian optimal than in the status-quo economy. This gap finally reaches 13 percentage points in the fourth period, 2018–2027, at which point all workers in the labor force were born after the initial date of 1988.

Because workers born before 1988 cannot re-adjust their occupational choices, the government can only use the direct redistribution mechanism to improve their welfare. As a result, there is a reason to tax robots initially in order to loosen the intensive-margin constraint of those non-routine workers. This is the reason why robot taxes are positive initially. As time goes by, the share of workers who did not readjust their skill choices decreases, which implies that there is less of a reason to distort robot use. As a result, the tax on robots declines over these initial periods. After these workers leave the labor force, there’s no longer any reason to tax robots.

**The role of endogenous skill acquisition** To isolate and clarify the effects of the endogenous nature of skill acquisition on the design of the tax system, we consider a model where the number of routine and non-routine workers follows an exogenous path. This path coincides with the equilibrium evolution of the number of routine and non-routine workers in our benchmark dynamic model.

Figure 8 compares the paths for the economies with endogenous and exogenous
skill acquisition, which we call ES and XS, respectively. This figure shows that routine workers receive a better allocation of consumption and hours worked in the exogenous-skills economy. The reason for this property is that, in the endogenous-skills economy, improving the allocation of routine workers reduces the incentive of the new generations to acquire non-routine skills. In fact, if the planner were to offer the allocations in the economy with exogenous skills in the economy with endogenous skills, the number of routine workers in the latter economy would fall by roughly 15 percent.

When skills are exogenous the planner taxes robots at higher rates than when skills are endogenous. With endogenous skills, robot taxes become zero in the period 2018-27. In contrast, with exogenous skills the tax rate on robots converges to zero only asymptotically. These properties follow from the fact that only the direct redistribution mechanism is relevant in the economy with exogenous skills.

**Initial conditions and time inconsistency** We now discuss the tension between the direct and indirect redistribution mechanisms. In our model, optimal policy must take into account the effect of redistribution on workers’ skill choices. If the planner redistributes too much to routine workers, the share of routine workers in the economy becomes very large. In our calibration, we find that optimal redistribution is limited in order to induce more agents to invest in non-routine skills.
This optimal plan is inherently time inconsistent. Since skills are chosen once-and-for-all when workers are young, older workers cannot readjust their skills. As a result, a plan that promises low redistribution to favor the acquisition of non-routine skills is only optimal ex ante, that is, before skill acquisition has been decided. The same planning problem starting at a later date would deviate from the original plan, and would use the direct redistribution mechanism to redistribute income towards older routine workers (the extensive margin would no longer be relevant for those workers). As a result, robots would be taxed.

We compute the optimal policy starting at 1988, at the onset of the automation era. We could alternatively have solved the problem starting in 2020, or at any future date, assuming that the status quo remains in place until that date. The optimal tax system starting today would differ from the plan designed in 1988 for two reasons. The first is the time inconsistency described above, which would result in optimal
taxation in the initial periods. The second is that the initial conditions which result from the status-quo policy are different from those that arise from the optimal policy. In particular, because the status quo features lower incentives for skill acquisition, there would be a larger pool of routine workers. This property would make the use of robot taxes all the more relevant.

6 Conclusions

Our analysis suggests that without changes to the current U.S. tax system, a sizable fall in the costs of automation will lead to a massive rise in income inequality.

We study the problem of a planner that implements a non-linear income tax system and linear robot taxes. Our model has an overlapping-generations structure that incorporates the life-cycle aspects of labor supply. Before entering the labor force, workers choose whether to acquire routine or non-routine skills. The cost of becoming a non-routine worker is heterogeneous across the population.

Designing an optimal tax system requires balancing two objectives. First, the planner wants to give the young generations incentives to invest in skills and become non-routine workers. Second, the planner wants to redistribute income towards routine workers, since their wages fall as robots become cheaper. Taxing robots reduces the non-routine wage premium and helps redistribute income towards routine workers.

In our calibrated economy, we find that it is optimal to tax robots while the initial old generations of routine workers are in the labor force. Once they retire, optimal robot taxes are zero. In other words, it is optimal to tax robots in the short run but not in the long run.

A Appendix

A.1 Appendix to section 3

A.1.1 The first-best allocation

We define the first-best allocation in this economy as the solution to an utilitarian welfare function, absent informational constraints. This absence implies that the planner can perfectly discriminate among agents and enforce any allocation that satisfies the aggregate resource constraint. The optimal plan solves the following problem

\[
W = \max \omega r \pi_r [u(c_r, l_r) + v(G)] + \omega_n \pi_n [u(c_n, l_n) + v(G)].
\]

\[
\pi_r c_r + \pi_n c_n + G \leq A \left[ \int_0^m x_i^p di + \int_m^1 n_i^p di \right]^{\frac{1-\alpha}{\rho}} (\pi_n l_n)^{\alpha} - \phi \int_0^m x_i di, \ [\mu],
\]

\[
\int_m^1 n_i di = \pi_r l_r, \ [\eta].
\]

The first-order conditions with respect to \( n_i \) and \( x_i \) are

\[
\mu (1 - \alpha) A \left[ \int_0^m x_i^p di + \int_m^1 n_i^p di \right]^{\frac{1-\alpha}{\rho} - 1} (\pi_n l_n)^{\alpha} n_i^{\rho - 1} = \eta, \ \forall i \in (m, 1]
\]

\[
(1 - \alpha) A \left[ \int_0^m x_i^p di + \int_m^1 n_i^p di \right]^{\frac{1-\alpha}{\rho} - 1} (\pi_n l_n)^{\alpha} x_i^{\rho - 1} = \phi, \ \forall i \in [0, m].
\]

The first equation implies that the marginal productivity of routine labor should be constant across the activities that use routine labor. This property means that \((1 - m) n_i = \pi_r l_r\) for \( i \in (m, 1] \) and \( n_i = 0 \), otherwise. The same property applies to robots used in the activities that are automated, \( x_i = x \) for \( i \in [0, m] \) and \( x_i = 0 \), otherwise.
To characterize the optimal allocations we replace \( n_i \) and \( x_i \) in the planner’s problem, which can be rewritten as

\[
W = \max \omega_r \pi_r \left[ u(c_r, l_r) + v(G) \right] + \omega_n \pi_n \left[ u(c_n, l_n) + v(G) \right].
\]

\[
\pi_r c_r + \pi_n c_n + G \leq A \left[ mx^\rho + (1 - m) \left( \frac{\pi_r l_r}{1 - m} \right)^{\frac{1 - \alpha}{\rho}} \right] \frac{N_n}{\rho} x^{\rho - 1} \pi_r \rho - \phi m x, \quad [\mu].
\]

The first-order conditions with respect to \( x \) and \( m \) are, respectively,

\[
(1 - \alpha) A \left[ m x^\rho + (1 - m) \left( \frac{\pi_r l_r}{1 - m} \right)^{\frac{1 - \alpha}{\rho}} \right] \frac{N_n}{\rho} x^{\rho - 1} = \phi,
\]

\[
\frac{1 - \alpha}{\rho} A \left[ m x^\rho + (1 - m) \left( \frac{\pi_r l_r}{1 - m} \right)^{\frac{1 - \alpha}{\rho}} \right] \frac{N_n}{\rho} \left[ x^\rho - (1 - \rho) \left( \frac{\pi_r l_r}{1 - m} \right)^{\rho} \right] = \phi x.
\]

The ratio of these two equations implies that if automation is positive, \( m \in (0, 1) \), then \( x = \pi_r l_r / (1 - m) \). Using this condition, we obtain

\[
W = \max \omega_r \pi_r \left[ u(c_r, l_r) + v(G) \right] + \omega_n \pi_n \left[ u(c_n, l_n) + v(G) \right].
\]

\[
\pi_r c_r + \pi_n c_n + G \leq A \left( \frac{\pi_r l_r}{1 - m} \right)^{1 - \alpha} (\pi_n l_n)^{\alpha} - \phi m \frac{\pi_r l_r}{1 - m}, \quad [\mu].
\]

The first-order condition with respect to the level of automation implies that

\[
(1 - \alpha) A \frac{1}{(1 - m)^{2 - \alpha}} (\pi_r l_r)^{1 - \alpha} (\pi_n l_n)^{\alpha} - \phi \frac{\pi_r l_r}{(1 - m)^2} = 0 \iff m = 1 - \left[ \frac{\phi}{A(1 - \alpha)} \right]^{1/\alpha} \frac{\pi_r l_r}{\pi_n l_n},
\]

provided that \( m \) is interior. Then,

\[
m = \max \left\{ 1 - \left[ \frac{\phi}{A(1 - \alpha)} \right]^{1/\alpha} \frac{N_r}{N_n}, 0 \right\}.
\]

The first-order conditions with respect to \( c_r, c_n, l_r, l_n, \) and \( G \) are

\[
\omega_r u_c(c_r, l_r) = \mu_r,
\]

\[
\omega_n u_c(c_n, l_n) = \mu_r,
\]
\[ \omega_r u_l(c_r, l_r) \geq \frac{\mu}{\pi r} (1 - \alpha)(1 - m) Y, \]
\[ \omega_n u_l(c_n, l_n) = \mu \frac{\alpha Y}{\pi n / n}, \]
\[ g'(G) = \mu. \]

The first-order condition with respect to \( N_r \) is presented with inequality, because the constraint \( N_r \geq 0 \) may bind when automation costs are low. The combination of the first two equations implies that
\[ \omega_r u_c(c_r, l_r) = \omega_n u_c(c_n, l_n). \]

The optimal marginal rates of substitution are given by the combination of the marginal utility of consumption and leisure for each individual
\[ \frac{u_l(c_r, l_r)}{u_c(c_r, l_r)} \geq (1 - \alpha)(1 - m) \frac{Y}{\pi r l_r}, \]
\[ \frac{u_l(c_n, l_n)}{u_c(c_n, l_n)} = \frac{\alpha Y}{\pi n l_n}. \]

Finally, from the first-order conditions for \( G \) and \( c_r \) it follows that
\[ g'(G) = \omega_r u'(c_r). \] (51)

**A.1.2 Necessity and sufficiency in the static model**

Worker optimality implies that the utility associated with the bundle of consumption and income assigned to agent \( j \), \( \{c_j, l_j\} \), must be at least as high as the utility associated with any other bundle \( \{c, l\} \) that satisfies the budget constraint \( c \leq w_j l - T(w_j l) \), implying that \( u(c_j, l_j) \geq u(c, l) \). In particular, routine workers must prefer their bundle, \( \{c_r, l_r\} \), to the bundle that they would get if they pretended to be non-routine workers while keeping the routine wage, \( \{c_n, w_n l_n / w_r\} \). Similarly, non-routine workers must prefer their bundle, \( \{c_n, l_n\} \), to the bundle they would get if
they pretended to be routine workers, \{c_r, w_r, l_r/w_n\}. These requirements correspond to the two IC constraints, (29), and (30), so these conditions are necessary.

We show in the Appendix that equation (28) is necessary by combining the first-order conditions to the firms’ problems with the resource constraint, (11). In addition, we show that conditions (28), (29), and (30) are also sufficient. To see that equations (29) and (30) summarize the worker problem, note that it is possible to choose a tax function such that agents prefer the bundle \{c_j, l_j\} to any other bundle. For example, the government could choose a tax function that sets the agent’s after-tax income to zero for any choice of \(w_jl\) different from \(w_jl_j\), \(j = n, r\). These results are summarized in the following proposition.

**Lemma 3.** Equations (28), (30) and (29) characterize the set of implementable allocations. These conditions are necessary and sufficient for a competitive equilibrium.

In an equilibrium, robot producers set the price of robots equal to their marginal cost

\[ p_i = \phi. \] (52)

Optimality for final goods producers implies that

\[ x_i = \begin{cases} \frac{\pi r l_r}{1 - m}, & i \in [0, m], \\ 0, & \text{otherwise} \end{cases} \] (53)

\[ n_i = \begin{cases} \frac{\pi r l_r}{1 - m}, & i \in (m, 1], \\ 0, & \text{otherwise} \end{cases} \] (54)

\[ m = \max \left\{ 1 - \left[ \frac{(1 + \tau^x)\phi}{(1 - \alpha)A} \right]^{1/\alpha} \frac{\pi r l_r}{\pi n l_n}, 0 \right\}, \] (55)

\[ Y = A \left[ \int_0^m x_i^0 d\bar{i} + \int_m^1 n_i^0 d\bar{i} \right]^{1/\rho} (\pi n l_n)^{\alpha}, \] (56)

\[ w_r = (1 - \alpha)(1 - m) \frac{Y}{\pi r l_r}. \] (57)
\[ w_n = \alpha \frac{Y}{\pi_n l_n}. \] (58)

The resource constraint is
\[ \pi_r c_r + \pi_n c_n + G \leq Y - \int_0^m \phi x_i, \] (59)

We can let equation (52) define the price of robots, equation (53) define \( x_i \), equations (54), (55) and (56) determine \( n_i, m, \) and \( Y \), respectively. Assuming that \( m \) is interior, the wage equations (57) and (58) can be written as (14) and (15). These equations can be used to solve for the equilibrium wage rates. Combining the results above, we can write the resource constraint as
\[ \pi_r c_r + \pi_n c_n + G \leq \alpha \left[ A^{1/\alpha} \frac{(1 - \alpha)^{1-\alpha}}{\alpha} \right] \frac{\tau^x + \alpha}{\alpha(1 + \tau^x)} \pi_n l_n + \phi \pi_r l_r. \]

Replacing the wage rates we can write
\[ \pi_r c_r + \pi_n c_n + G \leq \pi_n w_n l_n \frac{\tau^x + \alpha}{\alpha(1 + \tau^x)} + \pi_r w_r l_r. \] (60)

This derivation makes it clear that the resource constraint (60) summarize the equilibrium conditions of the production side of the economy.

Worker optimality requires that
\[ u(c_j, l_j) \geq u(c, l), \quad \forall (c, l) : c \leq w_j l - T(w_j l). \]

The following incentive constraint are necessary conditions
\[ u(c_n, l_n) \geq u \left( \frac{w_r}{w_n} l_r \right), \]
\[ u(c_r, l_r) \geq u \left( \frac{w_n}{w_r} l_n \right). \]

These are also sufficient conditions, because the planner can set the tax schedule \( T(\cdot) \) such that for all \( Y \not\in \{Y_n, Y_r\} \) the allocation is worse for both agents than their respective allocation. This goal can be accomplished by setting
\[ T(y) = y - \max \left\{ c | u(c_i, l_i) \geq u \left( c, \frac{y}{w_i} \right), \text{for } i = r, n \right\}. \]
Since the government can choose an arbitrary tax function, it is only bound by the incentive constraints which characterize the informational problem. This property means that the income tax function that is assumed here to implement the optimal allocation is without loss of generality. Any other implementation would at least have to satisfy the same two incentive constraints.

A.1.3 Proof of proposition 1

The allocations solve the original optimization problem, or equivalently they solve

$$W(\tau^x) = \max \pi_r \omega_r u(c_r, l_r) + \pi_n \omega_n u(c_n, l_n) + v(G)$$

subject to

$$[\eta_r \pi_r] \ u(c_r, l_r) \geq u \left( c_r \frac{w_n}{w_r} l_n \right),$$

$$[\eta_n \pi_n] \ u(c_n, l_n) \geq u \left( c_r \frac{w_r}{w_n} l_r \right),$$

$$[\mu] \ \pi_r c_r + \pi_n c_n + G \leq \pi_n w_n l_n \frac{\tau^x + \alpha}{\alpha (1 + \tau^x)} + \pi_r \frac{w_r l_r}{1 + \tau^x}.$$ 

Assume that the routine IC constraint does not bind, then $\eta_r = 0$. The envelope condition is

$$W'(\tau^x) = -\eta_n \pi_n u_l \left( c_r \frac{w_r}{w_n} l_r \right) \frac{d \log (w_r/w_n)}{d \log (1 + \tau^x)} \frac{1}{1 + \tau^x} \frac{w_r l_r}{w_n} + \mu \left[ \frac{\pi_n w_n l_n \frac{\tau^x + \alpha}{\alpha (1 + \tau^x)}^2}{d \log (1 + \tau^x)} + \frac{\pi_r \frac{w_r l_r}{1 + \tau^x}}{d \log (1 + \tau^x)} - 1 \right]$$

Using the wages we have that

$$w_r = \phi(1 + \tau^x) \Rightarrow \frac{d \log w_r}{d \log (1 + \tau^x)} = 1,$$

$$w_n = \frac{\alpha A^{1/\alpha} (1 - \alpha)^{1-\alpha}}{[(1 + \tau^x) \phi]^{1-\alpha}} \Rightarrow \frac{d \log w_n}{d \log (1 + \tau^x)} = -\frac{1 - \alpha}{\alpha},$$

$$\frac{w_r}{w_n} = \frac{[(1 + \tau^x) \phi]^{\frac{1}{\alpha}}}{\alpha A^{1/\alpha} (1 - \alpha)^{1-\alpha}} \Rightarrow \frac{d \log w_r/w_n}{d \log (1 + \tau^x)} = \frac{1}{\alpha}.$$
Plugging these into the envelope condition we obtain

\[ W'(\tau^x) = -\eta_n \pi_n u_l \left( c_r, \frac{w_r}{w_n} l_r \right) \frac{1}{\alpha (1 + \tau^x)} \frac{w_r l_r}{w_n} + \mu \pi_n w_n l_n \frac{\tau^x + \alpha}{\alpha (1 + \tau^x)^2} \left[ -\frac{1 - \alpha}{\alpha} + \frac{1 - \alpha}{\tau^x + \alpha} \right] \]

Because \( \mu > 0 \) then if \( \tau^x \leq 0 \) we obtain that

\[ W'(\tau^x) > 0, \]

so that the planner always improves its objective by marginally increasing \( \tau^x \). Since optimality implies that \( W'(\tau^x) = 0 \) then the optimal tax on robots satisfies the following condition

\[ \frac{\tau^x}{1 + \tau^x} = \frac{\alpha}{1 - \alpha} \frac{\eta_n}{\mu w_n l_n} \left( -u_l \left( c_r, \frac{w_r}{w_n} l_r \right) \frac{w_r l_r}{w_n} \right) \]

The first-order condition with respect to \( l_r \) implies that

\[ -\frac{\eta_n}{\mu} \frac{u_l}{u_l} \left( c_r, \frac{w_r}{w_n} l_r \right) \frac{w_r l_r}{w_n} = \frac{\tilde{\omega}_r \pi_r u_l \left( c_r, l_r \right) l_r + \pi_r w_n l_n}{\pi_n} \frac{\pi_r \phi l_r}{\pi_n} \left[ 1 - \frac{\tilde{\omega}_r \left( -u_l \left( c_r, l_r \right) \right)}{\phi} \right] \]

where \( \tilde{\omega}_r = \omega_r / \mu \). Replacing this equation in the optimal condition for \( \tau^x \) we obtain

\[ \frac{\tau^x}{1 + \tau^x} = \frac{\alpha}{1 - \alpha} \frac{\pi_r \phi l_r}{\pi_n w_n l_n} \left[ 1 - \frac{\tilde{\omega}_r \left( -u_l \left( c_r, l_r \right) \right)}{\phi} \right]. \]

A.1.4 The full automation case \((m = 1, l_r = 0)\)

If the optimal plan features \( l_r = 0 \) then it must be that \( l_n > 0 \). This result implies that \( \psi = 0 \). From the envelope condition we can see that

\[ W'(\tau^x) = -\frac{\mu}{\alpha (1 + \tau^x)} \pi_n w_n l_n \frac{\tau^x}{1 + \tau^x} \frac{1 - \alpha}{\alpha} = 0 \Leftrightarrow \tau^x = 0. \]
A.2 Appendix to section 4

A.2.1 Proof of lemma 1

First, note that the extensive margin incentive compatibility constraints can be equivalently written as

\[ U_{\theta,t} \geq U_{\theta',t} + \theta (s_{\theta,t} - s_{\theta',t}) \]  \( (62) \)

for all \( t \) and \( \theta, \theta' \in \Theta \).

First, suppose that \((62)\) are satisfied. Then, take \( \theta, \theta' \in \Theta \), i.e. such that \( s_t(\theta) = s_t(\theta') \). As a result, those conditions imply

\[ U_t(\theta) \geq U_t(\theta') \]
\[ U_t(\theta') \geq U_t(\theta) \]

which is equivalent to \( U_t(\theta) = U_t(\theta') \). This condition must hold for all \( \theta, \theta' \in \Theta_{j,t} \) for \( j = n, r \). Then, define \( U_{j,t} = U_t(\theta) \) for \( \theta \in \Theta_{j,t} \), which implies that \( U_t(\theta) = U_{j,t} \) for all \( \theta \in \Theta_{j,t} \). Then, define \( \theta^*_t = U_{n,t} - U_{r,t} \). For all \( \theta < \theta^*_t \) we have

\[ U_{n,t} - \theta > U_{r,t} \]  \( (63) \)

which implies that \( s_t(\theta) = 1 \). For all \( \theta > \theta^*_t \) we have

\[ U_{n,t} - \theta < U_{r,t} \]  \( (64) \)

which implies that \( s_t(\theta) = 0 \).

To show the reverse implication suppose that the conditions in the lemma hold. Then, for all \( \theta \in \Theta_{n,t} \) we have

\[ U_{\theta,t} = U_{n,t} = U_{\theta',t} \quad \forall \theta' \in \Theta_{n,t} \]
\[ \tilde{U}_{\theta,t} = U_{n,t} - \theta \geq U_{n,t} - \theta^* = U_{r,t} \quad \forall \theta' \in \Theta_{r,t}. \]

Instead, if \( \theta \in \Theta_{r,t} \), then

\[ U_{\theta,t} = U_{n,t} = U_{\theta',t} \quad \forall \theta' \in \Theta_{r,t} \]
\[ \tilde{U}_{\theta,t} = U_{r,t} = U_{n,t} - \theta^* \geq U_{n,t} - \theta = U_{\theta',t} - \theta \quad \forall \theta' \in \Theta_{n,t}. \]  

55
As a result, the allocation is extensive margin incentive compatible, i.e. it satisfies (62).

A.2.2 Proof of lemma 2

The proof strategy is as follows: take an allocation for which the properties in the lemma do not hold, and show that there exists a perturbation which strictly improves welfare. We start by showing that this allocation frees up resources, then show that it can deliver an increase in government spending which improves utility. Finally, we check that it still satisfies all constraints.

Define \( \Omega_{j,t} \equiv \pi_{j,t} \omega_{j,t} \), for \( t = 2 - L, ..., 0 \), \( \Omega_{j,t} \equiv \int_{\Omega_{j,t}} \omega_{\theta,t} h(\theta) d\theta \), and \( \Omega_t = \sum_{a=0}^{L-1} \sum_{j=n,r} \Omega_{j,t} \). We can write the optimal program as

\[
\max_{t=2-L, j=n,r} \sum_{a=0}^{\infty} \sum_{j=\infty}^{\infty} \beta^{\max\{0,t-1\}} \Omega_{j,t} \hat{U}_{j,t} + \sum_{t=1}^{\infty} \beta^{t-1} \Omega_t v(G_t) - \sum_{t=1}^{\infty} \int_0^{\theta_t^*} \beta^{t-1} \omega_{\theta,t} h(\theta) \theta d\theta \tag{65}
\]

\[
\hat{U}_{n,1-a} + \sum_{t=1}^{L_w-a} \beta^{t-1} \left[ \psi \left( l_{t,t}^{a+(t-1)} \right) - \psi \left( \frac{F_{r,t} l_{t,t}^{a+(t-1)}}{F_{n,t} l_{t,t}^{a+(t-1)}} \right) \right], a = 1, ..., L_w - 1 \tag{66}
\]

\[
\hat{U}_{r,1-a} + \sum_{t=1}^{L_w-a} \beta^{t-1} \left[ \psi \left( l_{t,t}^{a+(t-1)} \right) - \psi \left( \frac{F_{n,t} l_{t,t}^{a+(t-1)}}{F_{r,t} l_{t,t}^{a+(t-1)}} \right) \right], a = 1, ..., L_w - 1 \tag{67}
\]

\[
\hat{U}_{n,t} + \sum_{a=0}^{L_w-1} \beta^a \left[ \psi \left( l_{t,t}^{a+t} \right) - \psi \left( \frac{F_{r,t} l_{t,t}^{a+t}}{F_{n,t} l_{t,t}^{a+t}} \right) \right], \theta \in \Theta_{r,t}, t = 1, 2, ... \tag{68}
\]

\[
\hat{U}_{r,t} + \sum_{a=0}^{L_w-1} \beta^a \left[ \psi \left( l_{t,t}^{a+t} \right) - \psi \left( \frac{F_{n,t} l_{t,t}^{a+t}}{F_{r,t} l_{t,t}^{a+t}} \right) \right], \theta \in \Theta_{n,t}, t = 1, 2, ... \tag{69}
\]

\[
\theta^*_t = \hat{U}_{n,t} - \hat{U}_{r,t}, t = 1, 2, ... \tag{70}
\]

\[
\hat{U}_{j,1-a} = \sum_{t=1}^{L_w-a} \beta^{t-1} \left\{ c_{j,t}^{a+(t-1)} \right\} - \sum_{t=1}^{L_w-a} \beta^{t-1} \psi \left( c_{j,t}^{a+(t-1)} \right), a = 1, ..., L - 1, j = n, r \tag{71}
\]

\[
\hat{U}_{j,t} = \sum_{a=0}^{L_w-1} \beta^a \left\{ c_{j,t}^a \right\} - \sum_{t=1}^{L_w-a} \beta^a \psi \left( c_{j,t}^a \right), \theta \in \Theta_{j,t}, t = 1, 2, ..., j = n, r, \tag{72}
\]

plus the resource constraint (37).

**Labor supply** Take an allocation that satisfies all the constraints, and for which there exists a triplet \((t, a, j)\) such that for every \( \theta \in \Theta_{j,t}, a \), there exists a subset \( \Theta^* \subset \)
\( \Theta_{j,t-a} \), such that: (i) \( l^a_{\theta,t} \neq l^a_{\theta',t} \), for all \( \theta' \in \Theta^* \), and (ii) \( \int_{\Theta_j} h(\theta) d\theta > 0 \). The first property simply requires some dispersion in allocations and the second property requires that this set has non-null measure.

Consider the following perturbation: for all \( \theta \in \Theta_{j,t-a} \), define their new labor supply as \( l^a_{\theta,t} = l^a_{j,t} \equiv \int_{\Theta_{j,t-a}} l^a_{j,t} \frac{h(\theta)}{h(\theta')} d\theta \). Then, construct their new consumption, \( c^a_{\theta,t} = c^a_{j,t} \), such that

\[
U_{\theta,t-a} + u(c^a_{\theta,t}) - u(c^a_{\theta,t}) = U_{j,t} \iff u(c^a_{\theta,t}) - u(c^a_{\theta,t}) = \psi(l^a_{\theta,t}) - \psi(l^a_{\theta,t}),
\]

i.e., such that their utility is unchanged. Integrating on both sides, we obtain

\[
u(c^a_{j,t}) - \int_{\Theta_{j,t-a}} u(c^a_{\theta,t}) \frac{h(\theta)}{h(\theta')} d\theta = \psi(l^a_{j,t}) - \int_{\Theta_{j,t-a}} \psi(l^a_{\theta,t}) \frac{h(\theta)}{h(\theta')} d\theta. \tag{74}
\]

Since \( u \) is concave and \( \psi \) is convex, we know that

\[
\int_{\Theta_{j,t-a}} u(c^a_{\theta,t}) \frac{h(\theta)}{h(\theta')} d\theta \leq u \left( \int_{\Theta_{j,t-a}} c^a_{\theta,t} \frac{h(\theta)}{h(\theta')} d\theta \right)
\]

\[
\int_{\Theta_{j,t-a}} \psi(l^a_{\theta,t}) \frac{h(\theta)}{h(\theta')} d\theta > \psi \left( \int_{\Theta_{j,t-a}} l^a_{\theta,t} \frac{h(\theta)}{h(\theta')} d\theta \right) \Rightarrow \psi(l^a_{j,t}).
\]

As a result,

\[
u(c^a_{j,t}) = \int_{\Theta_{j,t-a}} u(c^a_{\theta,t}) \frac{h(\theta)}{h(\theta')} d\theta + \psi(l^a_{j,t}) - \int_{\Theta_{j,t-a}} \psi(l^a_{\theta,t}) \frac{h(\theta)}{h(\theta')} d\theta
\]

\[
< u \left( \int_{\Theta_{j,t-a}} c^a_{\theta,t} \frac{h(\theta)}{h(\theta')} d\theta \right)
\]

which implies that

\[
c^a_{j,t} < \int_{\Theta_{j,t-a}} c^a_{\theta,t} \frac{h(\theta)}{h(\theta')} d\theta,
\]  

because \( u \) is increasing.
Intuitively, these results tell us that this perturbation leads to the same $\hat{U}_{j,t-a}$ for all agents, but relaxes resources in the economy. There is no change in aggregate labor supply by the workers, but aggregate consumption is strictly lower. As a result, the government can increase spending

$$G_t = G_t + \int_{\Theta_{j,t-a}} \left[ \int_{\Theta_{j,t-a}} c_{\theta,t}^{a} \frac{h(\theta)}{h(\theta)} d\theta - c_{j,t}^{a} \right] > G_t,$$

which leads to an increase in welfare while still satisfying the resource constraints.

It remains to be shown that this allocation satisfies all other implementability conditions. Because we hold fixed $\{\hat{U}_{n,t}, \hat{U}_{r,t}\}$, equations (70) are satisfied for all $t$. Since we did not change allocations for agents born prior to $t = 1$, then (66), (67), and (71) are still satisfied. Equations (72) are still satisfied because we imposed them to construct $c_{j,t}^{a}$.

We just need to show that the intensive margin incentive constraints, (69) and (70), are still satisfied. Because allocations do not change for other workers, they are satisfied for all workers not in occupation $j$, and for all workers in occupation $j$ born in periods other than $t - a$. So, we only need to show that:

$$\hat{U}_{j,t-a} \geq \hat{U}_{j,t-a} + \sum_{a' = 0}^{L_{m_t}-1} \beta^{a} \left[ \psi \left( l_{\theta,t-a+a'}^{a'} \right) - \psi \left( \frac{F_{j,t-a+a'}}{F_{j,t-a+a'}^{t-a+a'}} l_{\theta,t-a+a'}^{a'} \right) \right].$$

for all $\theta \in \Theta_{j,t-a}$, where $l_{\theta,t}^{a} = l_{\theta,t}^{a'}$ and $l_{\theta,t-a+a'}^{a'} = l_{\theta,t-a+a'}^{a'}$ for $a' \neq a$.

Define $\Psi_{j,t}(l) \equiv \psi(l) - \psi \left( \frac{F_{j,t}}{F_{j,t-a}} \right)$. By convexity of $\psi$, $\Psi_{j,t}$ is increasing in $l$ if $F_{j,t}/F_{j,t-a} < 1$, and decreasing if $F_{j,t}/F_{j,t-a} \geq 1$. Then, if $F_{j,t}/F_{j,t-a} \geq 1$ take $\theta' \in \Theta_{j,t-a}$ such that $l_{\theta',t}^{a} < l_{\theta',t}^{a'}$, or if $F_{j,t}/F_{j,t-a} < 1$ take $\theta' \in \Theta_{j,t-a}$ such that $l_{\theta',t}^{a'} > l_{\theta',t}^{a}$. This result implies that $\Psi \left( l_{\theta',t}^{a'} \right) > \Psi \left( l_{\theta,t}^{a} \right)$.

Since for the original allocations:

$$\hat{U}_{j,t-a} \geq \hat{U}_{j,t-a} + \sum_{a' = 0}^{L_{m_t}-1} \beta^{a} \left[ \psi \left( l_{\theta,t-a+a'}^{a'} \right) - \psi \left( \frac{F_{j,t-a+a'}}{F_{j,t-a+a'}^{t-a+a'}} l_{\theta,t-a+a'}^{a'} \right) \right]$$

58
holds for all \( \theta \in \Theta_{j,t-a} \), then

\[
\hat{U}_{j,t-a} \geq \hat{U}_{j,t-a} + \sum_{a' = 0}^{L_w-1} \beta^a \left[ \psi \left( l_{\theta,t-a+a'}^{a'} \right) - \psi \left( \frac{F_{j,t-a+a'} \psi_{\theta,t-a+a'}}{F_{j,t-a+a'} \psi_{\theta,t-a+a'}} \right) \right] = \hat{U}_{j,t-a} + \sum_{a' = 0}^{L_w-1} \beta^a \left[ \psi \left( l_{\theta,t-a+a'}^{a'} \right) - \psi \left( \frac{F_{j,t-a+a'} \psi_{\theta,t-a+a'}}{F_{j,t-a+a'} \psi_{\theta,t-a+a'}} \right) \right] + \left[ \psi \left( l_{\theta,t}^{a} \right) - \psi \left( l_{\theta,t}^{a} \right) \right] \geq 0
\]

**Consumption** We showed that if \( s_{\theta,t} = s_{\theta',t} \), then \( l_{\theta,t+a}^{a} = l_{\theta',t+a}^{a} \) for \( a = 0, 1, \ldots, L_w - 1 \). We now want to show that the same is true for consumption. This result can be most easily seen from the first-order conditions which imply that

\[
\frac{u'(c_{\theta,t}^0)}{u'(c_{\theta,t+a}^0)} = \frac{u'(c_{\theta',t}^0)}{u'(c_{\theta',t+a}^0)} \tag{77}
\]

for all \( \theta, \theta' \). These equations combined with the fact that (72) implies that

\[
\sum_{a=0}^{L-1} \beta^a u \left( c_{\theta,t+a}^0 \right) = \sum_{a=0}^{L-1} \beta^a u \left( c_{\theta',t+a}^0 \right) \tag{78}
\]

for \( \theta, \theta' \) such that \( s_{\theta,t} = s_{\theta',t} \) delivers the intended result.

**A.2.3 Proof of proposition 2**

Denote by \( \beta_t \) the multiplier for the period \( t \)'s resource constraint, and \( \beta_{\min[0,t-1]} \eta_{j,t} \) the multiplier on period \( t \in \{2 - L, \ldots, 0, 1, 2, \ldots\} \) for workers in occupation \( j \)'s intensive margin incentive constraint.

The first-order condition with respect to \( X_t \) is given by

\[
\mu_t \left[ F_{X,t} - \phi_t \right] + \sum_{a=0}^{L_w-1} \eta_{n,t-a} \psi' \left( \frac{F_{n,t}}{F_{r,t}} l_{r,t}^{a} \right) \frac{dF_{n,t}}{dX_t} l_{n,t}^{a} + \sum_{a=0}^{L_w-1} \eta_{r,t-a} \psi' \left( \frac{F_{n,t}}{F_{r,t}} l_{r,t}^{a} \right) \frac{dF_{n,t}}{dX_t} l_{n,t}^{a} = 0 \tag{79}
\]
If the incentive constraints of routine workers do not bind, then \( \eta_{r,t-a} = 0 \). If the incentive constraints of at least one routine worker binds, then at least one \( \eta_{n,t-a} > 0 \), which implies that

\[
\sum_{a=0}^{L_{w}-1} \frac{\eta_{n,t-a}}{\mu_{t}} \psi' \left( \frac{F_{r,t}^{a}}{F_{n,t}^{a}} \right) l_{r,t}^{a} > 0.
\]

As a result,

\[
F_{X,t} = \phi_{t} - \frac{d F_{n,t}}{d X_{t}} \sum_{a=0}^{L_{w}-1} \frac{\eta_{n,t-a}}{\mu_{t}} \psi' \left( \frac{F_{r,t}^{a}}{F_{n,t}^{a}} \right) l_{r,t}^{a} > \phi_{t},
\]

(80)
because \( \frac{d F_{n,t}}{d X_{t}} / d X_{t} < 0 \).

### A.2.4 Normalizing dynamic model

We define the following normalized variables which are constant in the steady state:

<table>
<thead>
<tr>
<th>Parameter/Variable</th>
<th>Original Variable</th>
<th>Normalized Variable</th>
</tr>
</thead>
<tbody>
<tr>
<td>Consumption</td>
<td>( c_{j,t}^{a} = \phi_{t}^{\frac{1-a}{a}} c_{j,t}^{a} )</td>
<td>( \bar{c}<em>{j,t}^{a} = \phi</em>{t}^{\frac{1-a}{a}} c_{j,t}^{a} )</td>
</tr>
<tr>
<td>Government spending</td>
<td>( G_{t} = \phi_{t}^{\frac{-1-a}{a}} G_{t} )</td>
<td>( \bar{G}<em>{t} = \phi</em>{t}^{\frac{-1-a}{a}} G_{t} )</td>
</tr>
<tr>
<td>Robots</td>
<td>( X_{t} = \phi_{t}^{\frac{-1-a}{a}} X_{t} )</td>
<td>( \bar{X}<em>{t} = \phi</em>{t}^{\frac{-1-a}{a}} X_{t} )</td>
</tr>
<tr>
<td>Output</td>
<td>( Y_{t} = \phi_{t}^{\frac{-1-a}{a}} Y_{t} )</td>
<td>( \bar{Y}<em>{t} = \phi</em>{t}^{\frac{-1-a}{a}} Y_{t} )</td>
</tr>
<tr>
<td>Net Output</td>
<td>( NY_{t} = \phi_{t}^{\frac{-1-a}{a}} NY_{t} )</td>
<td>( \bar{NY}<em>{t} = \phi</em>{t}^{\frac{-1-a}{a}} NY_{t} )</td>
</tr>
<tr>
<td>Non-routine wage</td>
<td>( F_{n,t} = \phi_{t}^{\frac{1-a}{a}} F_{n,t} )</td>
<td>( \bar{F}<em>{n,t} = \phi</em>{t}^{\frac{1-a}{a}} w_{n,t} )</td>
</tr>
<tr>
<td>Routine wage</td>
<td>( F_{r,t} = \phi_{t}^{\frac{1-a}{a}} F_{r,t} )</td>
<td>( \bar{F}<em>{r,t} = \phi</em>{t}^{\frac{1-a}{a}} F_{r,t} )</td>
</tr>
</tbody>
</table>

With this normalization, we can write output, net-output, and wages, relative
wage, marginal productivity of robots, and automation as follows:

\[
Y_t = A \left[ \bar{X}^\varepsilon + \phi_t^\varepsilon N_{r,t}^\varepsilon \right]^{\frac{1-\alpha}{\varepsilon}} N_{n,t}^\alpha, \quad NY_t = Y_t - \bar{X}_t,
\]

\[
\bar{F}_{n,t} = \alpha A \left[ \bar{X}^\varepsilon + \phi_t^\varepsilon N_{r,t}^\varepsilon \right]^{\frac{1-\alpha}{\varepsilon}} N_{n,t}^\alpha, \quad \bar{F}_{r,t} = (1 - \alpha) A \left[ \bar{X}^\varepsilon + \phi_t^\varepsilon N_{r,t}^\varepsilon \right]^{\frac{1-\alpha}{\varepsilon}} N_{n,t}^\alpha \phi_t^\varepsilon N_{r,t}^{-1},
\]

\[
\frac{\bar{F}_{r,t}}{\bar{F}_{n,t}} = \frac{1 - \alpha}{\alpha} \frac{\phi_t^\varepsilon N_{r,t}^\varepsilon N_{n,t}}{N_{n,t}^\varepsilon N_{r,t}^\varepsilon}, \quad \bar{F}_{X,t} = (1 - \alpha) A \left[ \bar{X}^\varepsilon + \phi_t^\varepsilon N_{r,t}^\varepsilon \right]^{\frac{1-\alpha}{\varepsilon}} N_{n,t}^\alpha \bar{X}_t^{-1},
\]

\[
m_t = \frac{\bar{X}_t^\varepsilon}{\bar{X}^\varepsilon + \phi_t^\varepsilon N_{r,t}^\varepsilon}.
\]

**The detrended optimization problem**  First, define \( \Omega_{j,t} \equiv \pi_{j,t} \omega_{j,t} \), for \( t = 2 - L, \ldots, 0 \). \( \Omega_{j,t} \equiv \int_{\Omega_{j,t}} \omega_{j,t} h(\theta) d\theta \), and \( \Omega_t = \sum_{a=0}^{L-1} \sum_{j=n,r} \Omega_{j,t} \). We can define the optimal program as

\[
\max \left\{ \sum_{a=1}^{L-1} \sum_{j=n,r} \Omega_{j,t-a} \left\{ \sum_{l=1}^{L-a} \beta^{l-1} u_c (c_{j,t}^{a+l(t-1)}) - \sum_{l=1}^{L-a} \beta^{l-1} \psi (j_{j,t}^{a+l(t-1)}) \right\} 
+ \sum_{l=1}^{L-1} \sum_{j=n,r} \beta^{l-1} \Omega_{j,t} \left\{ \sum_{a=0}^{L-0} \beta^{a} u_c (c_{j,t+a}^{a}) - \sum_{l=1}^{L-1} \beta^{l-1} \psi (j_{j,t+a}^{a}) \right\} 
+ \sum_{l=1}^{L-1} \sum_{j=n,r} \beta^{l-1} \Omega_{j} v(G_t) - \sum_{l=1}^{L-1} \int_{0}^{\theta_t} \beta^{l-1} \omega_{j,t} h(\theta) d\theta \right\} \right. 
\]

\[
\text{s.to}
\]

\[
[\eta_{j,t-1-a}] \sum_{l=1}^{L-a} \beta^{l-1} u_c (c_{j,t}^{a+(l-1)}) - \sum_{l=1}^{L-a} \beta^{l-1} \psi (j_{j,t}^{a+(l-1)}) \geq \sum_{l=1}^{L-a} \beta^{l-1} u_c (c_{j,t}^{a+(l-1)}) - \sum_{l=1}^{L-a} \beta^{l-1} \psi (j_{j,t}^{a+(l-1)}) \]

\[
[\beta^{l-1}] \pi_{j,t-a} \geq \sum_{a=0}^{L-1} \pi_{j,t-a} c_{j,t}^{a} + G_t = A \left[ \bar{X}^\varepsilon + \phi_t^\varepsilon N_{r,t}^\varepsilon \right]^{\frac{1-\alpha}{\varepsilon}} N_{n,t}^\alpha \bar{X}_t^{-1},
\]

We define the Lagrange multipliers in parenthesis.
A.2.5 Optimal policy steady state

In what follows, we derive the steady state for all variables assuming that the aggregate allocations converge, i.e. assume that the allocations for aggregate consumption, \( \bar{C}_t \), aggregate labor supply \( \bar{N}_{j,t} \) for \( j = n, r \), robots \( X_t \), and \( \theta^*_t \), and government spending converge to an interior steady state.

Since \( \theta^*_t \rightarrow \theta^* \), then \( \pi_n,t = H(\theta^*_t) \rightarrow H(\theta^*) \equiv \pi_n \), and \( \pi_r,t \rightarrow \pi_t \equiv 1 - \pi_n \).

Furthermore, since \( \Omega_t v'(G_t) = \mu_t \) and both \( \Omega_t \rightarrow \Omega \) and \( G_t \rightarrow G \), then \( \mu_t \rightarrow \mu \).

In the balanced-growth path \( \phi_t \rightarrow 0 \) and \( F_{r,t}/F_{n,t} \rightarrow 0 \). As a result, the incentive compatibility of routine workers can never bind. This property is shown in the following lemma.

**Lemma 4.** Suppose that the allocations converge to a steady state growth path with interior automation, then \( \eta_{r,t-a} \rightarrow 0 \), for all \( a \).

**Proof.** Since \( \bar{\phi}_t \rightarrow 0 \), the optimal labor supply by agents with routine skills is \( l_{r,t} = 0 \). This property implies that the utility of a worker with routine skills converges to

\[
U_{r,t} \rightarrow \sum_{a=0}^{L-1} \beta^a \left[ u(\bar{c}^a_t) + v(G) \right] - \sum_{a=0}^{L_n-1} \beta^a \psi(0) \equiv U_r,
\]

while the utility from pretending to be a non-routine worker converges to \(-\infty\) since it must be that \( l_n > 0 \):

\[
\lim_{t \to \infty} \sum_{a=0}^{L-1} \beta^a \left[ u(\bar{c}^a_{n,t+a}) + v(G) \right] - \sum_{a=0}^{L_n-1} \beta^a \psi\left( \frac{F_{n,t+a}}{F_{r,t+a}} \right) = -\infty,
\]

as \( \frac{F_{n,t}}{F_{r,t}} \rightarrow +\infty \). \( \square \)

The first-order conditions with respect to consumption when young are given by:

\[
u'(\bar{c}^a_{n,t}) \left[ \Omega_{n,t} + (\xi_{t-a} + \eta_{n,t-a}) \right] = \mu_t \tau_{n,t}
\]

\[
u'(\bar{c}^a_{r,t}) \left[ \Omega_{r,t} - (\xi_{t-a} + \eta_{n,t-a}) \right] = \mu_t \tau_{r,t}
\]
Using these expressions we can make two important observations. First, they imply that
\[
\frac{u'(c^0_{ij,t})}{u'(c^a_{j,t+a})} = \frac{\mu_t}{\mu_{t+a}} \to 1,
\]
which implies that in the steady state \(c^a_j = c^0_j\) for all \(a = 1, \ldots, L - 1\). Second, these expressions imply that \(\psi_t + \eta_{n,t} \to \kappa\), for some \(\kappa \in \mathbb{R}\).

Because the detrended marginal productivity of routine workers falls to zero, then \(l^a_{r,t} \to 0\) for all \(a\). As a result, in the steady state, the labor supply of non-routine workers of age \(\tau\) is given by the following condition:
\[
u'(l^a_n)(\Omega_n + \xi_t + \eta_{n,t}) = \pi_n \mu \bar{F}_n e_n.
\]
As a result, \(l^a_{n,t} \to l^a_n\).

Furthermore, the marginal condition with respect to robots is simply
\[
\bar{F}_X = 1 \Leftrightarrow \bar{X}_t = [(1 - \alpha)A]^{1/\alpha} N_n,
\]
and
\[
\bar{F}_n = \alpha A^{1/\alpha} (1 - \alpha)^{\frac{1-\alpha}{\alpha}}.
\]

From the first-order condition, we then obtain that \(\xi_t \to \bar{\xi}\) which solves
\[
\bar{\xi} = h(\theta^*) \mu \left[ \sum_{a=0}^{L-1} \beta^a (c^a_r - c^a_n) + \sum_{a=0}^{L-1} \beta^a e_n \right],
\]
which also implies that \(\eta_{n,t} \to \eta_n\).

The necessary and sufficient conditions to solve for an interior steady state are the following:

1. Consumption and government spending:
\[
u'(c^a_r)(\Omega_r - \bar{\xi} - \eta_r) = \mu \pi_r, \quad u'(c^a_n)(\Omega_n + \bar{\xi} + \eta_n) = \mu \pi_n. \tag{81}
\]
and
\[
C = \sum_{a=0}^{L-1} (c^a_r + c^a_n), \quad \Omega v'(G) = \mu. \tag{82}
\]

2. Labor supply:
\[
l^a_r = 0, \quad \psi'(l^a_n) (\Omega_n + \psi + \eta_n) = \mu F_n \pi_n e_a. \tag{83}
\]
and
\[
N_r = 0, \quad N_n = \sum_{a=0}^{L_w-1} \pi_n e_a l^a_n. \tag{84}
\]

3. Robots:
\[
\bar{X} = [(1 - \alpha) A]^{1/\alpha} N_n. \tag{85}
\]

4. Skill acquisition cut-off \( \theta^* \)
\[
\zeta = h(\theta^*) \mu \left[ \sum_{a=0}^{L-1} \beta^a (c^a_r - c^a_n) + \sum_{a=0}^{L_w-1} \beta^a \bar{F}_n e_a l^a_n \right],
\]

5. Intensive margin incentive compatibility, which need not necessarily bind:
\[
\theta^* \geq 0, \quad \eta_n \geq 0, \quad \eta_n \theta^* = 0, \tag{86}
\]

6. Extensive margin incentive compatibility
\[
\theta^* = \sum_{a=0}^{L-1} \beta^a [u(c^a_n) - u(c^a_r)] - \sum_{a=0}^{L_w-1} \beta^a [\psi(l^a_n) - \psi(0)], \tag{87}
\]

7. Resource constraint
\[
C + G = F_n N_n. \tag{88}
\]

We have \( 9 + 2L + 2L_w \) equations in

\[
\{ \{ c^a_n, c^a_r \}_{a=0, \ldots, L-1}, \{ l^a_n, l^a_r \}_{a=0, \ldots, L_w-1}, C, G, N_r, N_n, \bar{X}, \theta^*, \mu, \psi, \eta_n \},
\]

which are \( 9 + 2L + 2L_w \) unknowns.
A.2.6   Proof of proposition 3

In the balanced-growth path, we have that \( \eta_{r,a} = 0 \) and \( I_t^a = 0 \). As a result,

\[
\mu \left[ F_X - 1 \right] + \sum_{a=0}^{L_w-1} \eta_{n,a} \psi' \left( \frac{F_r}{F_n} \right) \frac{dF_r}{dX_t} l_t^a + \sum_{a=0}^{L_w-1} \eta_{r,a} \psi' \left( \frac{F_n}{F_r} \right) \frac{dF_n}{dX_t} l_t^a = 0
\]

reduces to

\[
F_X = 1.
\]

A.3   Appendix to section 5

A.3.1   Status-quo equilibrium equations

Below, we summarize the equilibrium equations for our model. We define the following variables:

\[
q_{t,a} \equiv \prod_{s=0}^{a-1} R_{t+a}^{-1}
\]  

(89)

for \( a > 0 \), and \( q_{t,t} \equiv 1 \).

**Workers born at** \( t \geq 1 \)  The consumption policy function is:

\[
e_{j,t+a} = \frac{\beta^a}{q_{t,t+a}} \frac{1 - \beta}{1 - \beta} W_{j,t}^0
\]

(90)

for \( t \geq 0 \) and \( a = 0, ..., L - 1 \). Here,

\[
W_{j,t}^0 \equiv \sum_{a=0}^{L_w-1} q_{t,a} \lambda_{t+a} \left( w_{j,t+a} \lambda_t l_t^a \right)^{1 - \gamma}.
\]

(91)

The labor supply is given by

\[
l_{j,t+a}^a = \left[ \frac{q_{t,a} \lambda_{t+a} \left( w_{j,t+a} \lambda_t \right)^{1 - \gamma}}{\beta^a \lambda_t \left( w_{j,t+1} \right)^{1 - \gamma}} \right]^{\frac{1}{\gamma}} l_{j,t}^0
\]

(92)
and

\[
\varrho_{j,t}^0 = \left[ \frac{1 - \beta^L 1 - \gamma}{1 - \beta} \right]_{\sum_{s=0}^{L_w-1} \beta^{-a_{1-s} 1 - \gamma} \left[ \frac{q_{t+s} \lambda_{t+s} (w_{j,t+s} e_s)^{1-\gamma}}{\lambda_t (w_{j,t} e_0)^{1-\gamma}} \right]}^{1_{1-s} 1 - \gamma} (93)
\]

for \( t \geq 0 \) and \( a = 0, ..., L - 1 \).

Solving for \( c_{j,t+a}^a \) and \( l_{j,t+a}^a \) we can compute asset holdings recursively

\[
b_{j,t+a}^a = R_{t+a} \left[ b_{j,t+a-1}^{a-1} + \lambda_{t+a} (w_{j,t+a} e_a l_{j,t+a}^a)^{1-\gamma} - c_{j,t+a}^a \right] (94)
\]

for \( a = 0, 1, ..., L - 1 \) using the fact that \( b_{j,t+1}^0 = 0 \), and

\[
b_{j,t+a}^a = R_{t+a} \left[ b_{j,t+a-1}^{a-1} - c_{j,t+a}^a \right] (95)
\]

for \( a = L, ..., L - 1 \).

Skill acquisition is determined by a threshold rule, which implies that the share of non-routine workers is given by

\[
\pi_{n,t} = H(\theta^*_t), \quad \pi_{r,t} = 1 - \pi_{n,t} (96)
\]

where

\[
\theta^*_t = \sum_{a=0}^{L-1} \beta^a \log c_{n,t+a}^a - \sum_{a=0}^{L-1} \beta^a \nu (l_{n,t+a}^a) - \sum_{a=0}^{L-1} \beta^a \log c_{r,t+a}^a + \sum_{a=0}^{L-1} \beta^a \nu (l_{r,t+a}^a) (97)
\]

Workers born at \( t = 2 - L_w, ..., 0 \) The consumption policy function is:

\[
c_{j,s}^{a+s-1} = \frac{\beta^{s-1} 1 - \beta}{q_1 s} \frac{1 - \beta^{s-a}}{1 - \beta^{L-a}} \mathcal{W}_{j,1}^a (98)
\]

for \( s = 1, ..., L - a \) and \( a = 1, ..., L_w - 1 \), where

\[
\mathcal{W}_{j,1}^a = \sum_{s=1}^{L_w-a} q_1 s \lambda_s \left( w_{j,s} e_{a+s-1} l_{j,s}^{a+s-1} \right)^{1-\gamma} + R_0 b_{j,0}^a (99)
\]
Here $b_{j,0}^{s-1}$ denotes the exogenous level of financial wealth that these agents enter the economy with.

Labor supply is given by

$$l_{j,s}^{a+s-1} = \left[ \frac{q_{1,s} \lambda_s (w_{j,s} e_{a+s-1})^{1-\gamma}}{\beta^{s-1} \lambda_1 (w_{j,1} e_a)^{1-\gamma}} \right] \frac{1}{\gamma+1} l_{j,1}^a,$$

for $s = 1, ..., L_w - a$ and $a = 1, ..., L_w - 1$, and

$$l_{j,1}^a = \left[ \frac{1 - \gamma (1 - \beta^{L-a})}{\gamma (1 - \beta)} \right] \left[ \sum_{s=1}^{L_w-a} \beta^{-(s-1)(1-\gamma)} \left[ q_{1,s} \frac{\lambda_s (w_{j,s} e_{a+s-1})^{1-\gamma}}{\lambda_1 (w_{j,1} e_a)^{1-\gamma}} \right] \frac{1}{\gamma+1} \right]^{1+\gamma}.$$

for $a = 1, ..., L_w - 1$.

Solving for $c_{j,t+a}^a$ and $l_{j,t+a}^a$ we can calculate asset holdings recursively

$$b_{j,s}^{a+s-1} = R_s \left[ b_{j,s-1}^{a+s-2} + \lambda_s (w_{j,s} e_{a+s-1} l_{j,s}^{a+s-1})^{1-\gamma} - c_{j,s}^{a+s-1} \right]$$

for $s = 1, ..., L_w - a$ using the fact that $b_{j,0}^{a-1}$ is exogenous, and

$$b_{j,s}^{a+s-1} = R_s \left[ b_{j,s-1}^{a+s-2} - c_{j,s}^{a+s-1} \right]$$

for $s = L_w - a + 1, ..., L - a$. This is done for $a = 1, ..., L_w - 1$.

**Workers born at $t = 2 - L, ..., 1 - L_w$** The consumption policy function is:

$$c_{j,s}^{a-1+s} = \frac{\beta^{s-1}}{q_{1,s}} \frac{1 - \beta}{1 - \beta^{L-a}} b_{j,0}^{a-1},$$

for $s = 1, ..., L - a$ and $a = L_w, ..., L - 1$.

We can solve for asset holdings recursively

$$b_{j,s}^{a+s-1} = R_s \left[ b_{j,s-1}^{a+s-2} - c_{j,s}^{a+s-1} \right]$$

for $s = 1, ..., L - a$ and $a = L_w, ..., L - 1$.
using the fact that $b_{j,0}^{a-1}$ is exogenous, for $s = 1, \ldots, L - a$. This is done for $a = 1, \ldots, L - w - 1$.

**Firm’s problem** The first-order conditions with respect to routine labor, robots and non-routine labor are as follows:

$$w_{r,t} = (1 - \alpha) A \left[ X_{t}^{\frac{\epsilon - 1}{\gamma}} + N_{r,t}^{\frac{\epsilon - 1}{\gamma}} \right]^{\frac{\epsilon (1 - \alpha)}{\gamma - 1}} N_{n,t}^{\frac{\epsilon - 1}{\gamma}}^{1 - \frac{1}{\gamma}}, \quad (106)$$

$$\phi_t = (1 - \alpha) A \left[ X_{t}^{\frac{\epsilon - 1}{\gamma}} + N_{r,t}^{\frac{\epsilon - 1}{\gamma}} \right]^{\frac{\epsilon (1 - \alpha)}{\gamma - 1}} N_{n,t}^{\frac{\epsilon - 1}{\gamma}}^{1 - \frac{1}{\gamma}}, \quad (107)$$

$$w_{n,t} = \alpha A \left[ X_{t}^{\frac{\epsilon - 1}{\gamma}} + N_{r,t}^{\frac{\epsilon - 1}{\gamma}} \right]^{\frac{\epsilon (1 - \alpha)}{\gamma - 1}} N_{n,t}^{\frac{\epsilon - 1}{\gamma}}^{1 - \frac{1}{\gamma}}. \quad (108)$$

**Government’s budget constraint**

$$G_t + B_{t-1} = \sum_{a=0}^{L_{w} - 1} \sum_{j=r}^{L_{w} - 1} \pi_{t-a} \left\{ w_{j,t} e_{a}^{l_{j,t}} - \lambda_{t} \left( w_{j,t} e_{a}^{l_{j,t}} \right)^{1 - \gamma} \right\} + \frac{B_{t}}{R_{t}} \quad (109)$$

**Market clearing** The market-clearing condition for aggregate labor supply is

$$N_{j,t} = \sum_{a=0}^{L_{w} - 1} \pi_{j,t-a} e_{a}^{l_{j,t}}. \quad (110)$$

Aggregate consumption, $C_t$ is given by

$$C_t = \sum_{a=0}^{L - 1} \sum_{j=r, n} \pi_{j,t-a} e_{a}^{l_{j,t}} \quad (111)$$

The goods market-clearing condition is

$$C_t + G_t = F(X_t, N_{r,t}, N_{n,t}) - \phi_t X_t. \quad (112)$$
The asset-market clearing condition is

$$\sum_{a=0}^{l-2} \sum_{j=n,r} \pi_{j,t-a} b_{j,t}^{a} = B_{t}. \quad (113)$$

</table>

**Pre-automation steady state** We start by solving for a steady state with $X = 0$, and for the non-detrended variables. For this initial steady state, we take occupations as being exogenous and set $\pi_{n} = 0.4356$ constant across generations to match the data on occupations. We also set $G/C = 0.2126$ and $B/C = 0.0427$.

We use a root finding algorithm to calibrate the discount factor $\beta$, the labor disutility parameter $\zeta$, the share of non-routine workers in production $\alpha$, and the steady
state interest rate $R$, that is a steady state equilibrium, and which verify that:

\[ \beta R = 1, \]
\[ \sum_{\tau=0}^{L_{\bar{w}}-1} \sum_{j=\pi_{\tau}}^{\bar{w}} \pi_{\tau} l_{\tau}^j = 1/3, \]
\[ \frac{w_n}{w_r} = 1.1943. \]

The assumption that $\beta R = 1$ is consistent with Gourinchas and Parker (2002), the second condition implies that the average labor supply is equal to one third, while the final condition implies that the non-routine wage premium matches that in the data.

**Transition dynamics** First, we solve the final steady state equilibrium. In this steady state, $\pi_{\tau} = 1$ and $l_{\tau}^j$ for all $\tau$. As a result,

\[ \bar{X} = [(1 - \alpha) A]^{1/\alpha} N_n, \]

and

\[ \bar{w}_r = 0, \quad \bar{w}_n = \alpha A^{1/\alpha} (1 - \alpha)^{1-\alpha}. \]

Computing this steady steady requires a simple iteration on the equilibrium real interest rate. In checking for a steady-state equilibrium, we always look for a solution which satisfies asset market clearing rather than good’s market clearing. From Walras’ law, if the asset market clears then so does the goods market. Auclert and Rognlie (2018) note that it may be problematic to look a solution which satisfies only the goods market clearing. This is because, in a steady state, satisfying the goods market clearing and every budget constraint only implies assets market clearing if the interest rate is not one, i.e., $R \neq 1$.

We use the transition to calibrate the parameters $\{\bar{\phi}_\phi, g, \epsilon, \mu, \sigma\}$. These parameters are chosen so that the competitive equilibrium matches the wage premium and
occupation shares. The procedure minimizes a sum of square deviations between
the equilibrium and the data.

To solve for the equilibrium, we take the asset distribution and occupation shares
in the initial steady state and compute a perfect foresight transition to this final
steady state. We assume that convergence occurs after $T$ periods (for our baseline
exercise, we set $T = 50$). Given $\{w_{n,t}, w_{r,t}, R_t, \lambda_t\}_{t=0}^T$, we can solve every household
problem to obtain consumption and labor at all periods and ages. As a result, we
can also solve for $\theta^*_t$ for all $t$, and then $\pi_{n,t}$ and $\pi_{r,t}$. Furthermore, we can back out
$b_{j,t}^\tau$.

Aggregating these variables we obtain $C_t = \sum_{\tau=0}^{L-1} \sum_{j=n,r} \pi_{j,t-\tau}c_{j,t}^\tau$ and $N_{j,t} = \sum_{\tau=0}^{L-1} \pi_{j,t-\tau}e_{j,t}^\tau$. Because we have fixed the spending-to-consumption and the debt-
to-consumption ratios, we can use $C_t$ to also back out $G_t$ and $B_t$ for all $t$. Furthermore,
we can use the first-order condition with respect to robots, to solve for $X_t$.

Given these solutions and the initial guesses $\{w_{n,t}, w_{r,t}, R_t, \lambda_t\}_{t=0}^T$, we check a set
of 4 equations every period:

$$
\Delta_{1,t} \equiv w_{r,t} - \phi_t^\frac{\epsilon}{\alpha} (1 - \alpha) A \left[ \bar{X}_t^\epsilon + \phi_t^\frac{\epsilon}{\alpha} N_{r,t}^\epsilon \right]^{1-\alpha} N_{n,t}^\alpha N_{r,t}^{\epsilon-1},
$$

$$
\Delta_{2,t} \equiv w_{n,t} - \alpha A \left[ \bar{X}_t^\epsilon + \phi_t^\frac{\epsilon}{\alpha} N_{r,t}^\epsilon \right]^{1-\alpha} N_{n,t}^\alpha N_{r,t}^{\epsilon-1},
$$

$$
\Delta_{3,t} \equiv \bar{G}_t + \bar{B}_{t-1} - \sum_{a=0}^{L-1} \sum_{j=n,r} \pi_{t-a} \left\{ w_{j,t} e_a l_{j,t}^a - \bar{L}_t \left( w_{j,t} e_a l_{j,t}^a \right)^{1-\gamma} \right\} - \frac{\bar{B}_t}{\bar{K}_t},
$$

$$
\Delta_{4,t} \equiv \sum_{a=0}^{L-2} \sum_{j=n,r} \pi_{j,t-a} b_{j,t-a}^a - \bar{B}_t.
$$

Formally, the model provides a mapping from $X \equiv \{w_{n,t}, w_{r,t}, R_t, \lambda_t\}_{t=0}^{T-1}$ to $\Delta \equiv \{\Delta_{1,t}, \Delta_{2,t}, \Delta_{3,t}, \Delta_{4,t}\}_{t=0}^{T-1}$, we denote this mapping by $M : \mathbb{R}^{4T} \to \mathbb{R}^{4T}$. An equilib-
rium is $X$ such that $M(X) = 0$.

Because ultimately our goal is to perform the calibration exercise, we need to
solve this equilibrium several times. Computational speed is important. We adopt
an easy to implement insight from Auclert et al. (2019), which involves a quasi-
Newton method using the approximate Jacobian, \(dM(\mathbf{X})/d\mathbf{X}|_{\mathbf{X}=\mathbf{X}_0}\), around a given point, \(\mathbf{X}_0\). For this procedure, we use the point \(\mathbf{X}_0 = \{w^0_{n,t}, w^0_{r,t}, \lambda, R\}_{t=0}^{T-1}\), where \(\lambda\) and \(R\) denote the steady state levels of these variables, and \(\mathbf{w}_{j,t}\) is computed as follows: we set \(N_{j,t} = N\) in the final steady state, we back out the path for \(\mathbf{X}_t\) from the first-order condition, and then use these paths to compute wages. It turns out that this approximation works reasonably well, and we usually obtain convergence in a few iterations.

A.4 Optimal Mirrleesian Policy

Because our calibration finds \(\varepsilon = 1\), we specialize this presentation to this case. Assuming that automation is interior (which we verify ex-post), we can change variables as in the static model, i.e., instead of \(\mathbf{X}_t\) we use the variable \(\tau_{t}^x\), which is such that

\[
\mathbf{X}_t = \left[ \frac{(1 - \alpha)A}{1 + \tau_{t}^x} \right] N_{n,t} - \phi_t^{1/\alpha} N_{r,t}.
\]

This change of variables also implies that

\[
NY_t = A^{\frac{\alpha}{\gamma}} \frac{(1 - \alpha) \frac{1 - \alpha}{\alpha} \tau_{t}^x + \alpha N_{n,t} + \phi_t^{\frac{1}{\alpha}} N_{r,t}}{(1 - \tau_{t}^x) \frac{1 - \alpha}{\alpha} + \tau_{t}^x N_{n,t} + \phi_t^{\frac{1}{\alpha}} N_{r,t}}
\]

and that relative wages are:

\[
\frac{F_r,t}{F_n,t} = \frac{1 - \alpha}{\alpha} \phi_t^{\frac{1}{\alpha}} \left[ \frac{1 + \tau_{t}^x}{(1 - \alpha) A} \right]^{\frac{1}{\gamma}}.
\]

The optimal plan solves the following program:

\[
\max_{\mathbf{\beta}} \sum_{t=1}^{\infty} \beta_t \sum_{i=r,n} \left\{ \sum_{\tau=0}^{L-1} \beta_t^{\tau} \pi_{i,t-\tau} \log (c_{i,t}^\tau) - \sum_{\tau=0}^{L_{\omega}-1} \beta_t^{\tau} \pi_{i,t-\tau} v (l_{i,t}^\tau) \right\} - \sum_{t=1}^{\infty} \beta_t \int_{-\infty}^{\infty} h (\theta) \theta d\theta + \sum_{t=1}^{\infty} \beta_t L_{\chi} \log (G_t)
\]

\[
[\beta_t^T \mu_t] \sum_{i=r,n} \sum_{\tau=0}^{L-1} \pi_{i,t-\tau} c_{i,t}^\tau + G_t \leq A^{\frac{\alpha}{\gamma}} \left[ \frac{1 - \alpha}{\alpha} \frac{\tau_{t}^x + \alpha}{1 + \tau_{t}^x} \right] \frac{1 - \alpha}{\gamma} \left[ \frac{1 - \alpha}{\alpha} \frac{1 + \tau_{t}^x N_{n,t} + \phi_t^{\frac{1}{\alpha}} N_{r,t}}{1 + \tau_{t}^x N_{n,t} + \phi_t^{\frac{1}{\alpha}} N_{r,t}} \right]
\]
\[ \theta^* = \left\{ \sum_{\tau=0}^{L-1} \beta_i^{\tau} \log (\tau_{n,t+\tau}^{\tau} - \sum_{\tau=0}^{L_w-1} \beta_i^{\tau} v (I_{n,t+\tau}^{\tau}) \right\} - \left\{ \sum_{\tau=0}^{L-1} \beta_i^{\tau} \log (\tau_{r,t+\tau}^{\tau} - \sum_{\tau=0}^{L_w-1} \beta_i^{\tau} v (I_{r,t+\tau}^{\tau}) \right\} \]

\[ \sum_{s=0}^{L-1-\tau} \beta_i^{s} \log (\tau_{n,1+s}^{s}) - \sum_{s=0}^{L_w-1-\tau} \beta_i^{s} v (I_{n,1+s}^{s}) \geq \sum_{s=0}^{L-1-\tau} \beta_i^{s} \log (\tau_{r,1+s}^{s}) - \sum_{s=0}^{L_w-1-\tau} \beta_i^{s} v \left( \frac{F_{r,1+s}^{s} I_{r,1+s}^{s}}{F_{n,1+s}^{s}} \right) \]

\[ \sum_{s=0}^{L-1} \beta_i^{s} \log (\tau_{n,1+s}^{s}) - \sum_{s=0}^{L_w-1} \beta_i^{s} v (I_{n,1+s}^{s}) \geq \sum_{s=0}^{L-1} \beta_i^{s} \log (\tau_{r,1+s}^{s}) - \sum_{s=0}^{L_w-1} \beta_i^{s} v \left( \frac{F_{r,1+s}^{s} I_{r,1+s}^{s}}{F_{n,1+s}^{s}} \right) \]

where in parenthesis we write the Lagrange multipliers.

**Optimality conditions** We assume, and verify later, that the intensive-margin incentive compatibility of routine workers never binds.

1. First-order conditions with respect to \( \tau_{r,1}^{i} \) for \( \tau \geq L_w \) (those that do not work anymore)

\[ \tau_{r,1}^{i} = \frac{1}{\mu_i} \]

2. First order conditions with respect to \( \tau_{r,1+s}^{i} \) for \( 1 \leq \tau \leq L_w - 1 \) these then are \( s = 0, 1, \ldots, L - 1 - \tau \) (these do not have extensive margin IC)

\[ \frac{\pi_{r,1-\tau} - \eta_{n,1}^{r}}{c_{r,1+s}^{r+s}} = \mu_{1+s} \pi_{r,1-\tau} \iff c_{r,1+s} = \frac{1 - \eta_{n,1}^{r}}{\mu_{1+s}} \]

\[ \frac{\pi_{r,1-\tau} + \eta_{n,1}^{r}}{c_{r,1+s}^{r+s}} = \mu_{1+s} \pi_{r,1-\tau} \iff c_{n,1+s} = \frac{1 + \eta_{n,1}^{r}}{\mu_{1+s}} \]

3. First order conditions with respect to \( I_{r,1+s}^{r+s} \) for \( 1 \leq \tau \leq L_w - 1 \), these then are for \( s = 0, 1, \ldots, L_w - 1 - \tau \). For routine workers:

\[ \phi' \left( I_{r,1+s}^{r+s} \right) \left\{ \pi_{r,1-\tau} - \eta_{n,1-\tau} \left( \frac{F_{r,1+s}^{r+s}}{F_{n,1+s}^{r+s}} \right)^{1+v} \right\} = \pi_{r,1-\tau} e_{r+s} \mu_{1+s} \]

73
\( \Leftrightarrow l_{r,t}^{\tau + s} = \left[ \frac{\pi_{r,1} e_{1+1} + s e_{r_1+1}}{\pi_{r,1} e_{1+1} + s e_{r_1+1} + \frac{1}{\eta_{1+1}}} \right]^{\frac{1}{\tau}} \)

For non-routine workers

\[ \nu' \left( l_{r,t}^{\tau + s} \right) \left[ \pi_{n,1} e_{1+1} + \eta_{1+1} \right] = \pi_{n,1} e_{1+1} + s E_{n,1+1} \]

4. Consumption \( c_{i,t+\tau}^r \), i.e. for those born in period \( t \geq 1 \). For routine workers

\[ \frac{\pi_{r,t} - \psi_t - \eta_{n,t}}{c_{r,t}^r} = \mu_{t+\tau} \pi_{r,t} \Leftrightarrow c_{r,t+\tau}^r = \frac{1 - \psi_t + \eta_{n,t}}{\mu_{t+\tau}} \]

For non-routine workers

\[ \frac{\pi_{n,t} + \psi_t + \eta_{n,t}}{c_{n,t+\tau}^r} = \mu_{t+\tau} \pi_{n,t} \Leftrightarrow c_{n,t+\tau}^r = \frac{1 + \psi_t + \eta_{n,t}}{\mu_{t+\tau}} \]

5. Government spending \( G_t \)

\[ \frac{L_X}{G_t} = \mu_t \Leftrightarrow G_t = \frac{L_X}{\mu_t} \]

6. Labor supply \( l_{i,t}^{\tau + \tau} \), i.e. for those born in period \( t \geq 1 \). For routine workers

\[ \nu' \left( l_{r,t}^{\tau + \tau} \right) \left( \pi_{r,t} - \psi_t \right) - \eta_{n,t} \nu' \left( \frac{F_{r,t}^{\tau + \tau}}{F_{n,t}^{\tau + \tau}} l_{r,t}^{\tau + \tau} \right) \frac{F_{r,t}^{\tau + \tau}}{F_{n,t}^{\tau + \tau}} = e_{r,\tau} \pi_{r,t} \mu_{t+\tau} E_{r,t+\tau} \]

\[ \nu' \left( l_{r,t}^{\tau + \tau} \right) \left( \pi_{r,t} - \psi_t - \eta_{n,t} \left( \frac{F_{r,t}^{\tau + \tau}}{F_{n,t}^{\tau + \tau}} \right)^{1+v} \right) = e_{r,\tau} \pi_{r,t} \mu_{t+\tau} E_{r,t+\tau} \]

For non-routine workers

\[ \nu' \left( l_{n,t}^{\tau + \tau} \right) \left[ \pi_{n,t} + \psi_t + \eta_{n,t} \right] = e_{r,\tau} \pi_{n,t} \mu_{t+\tau} E_{n} \]

7. First-order condition with respect to the tax \( \tau_{X,t} \) (missing)

\[ \sum_{\tau=0}^{L-1} \beta^{\tau} e_{n,t-\tau} \nu' \left( \frac{F_{r,t}^{\tau}}{F_{n,t}^{\tau}} l_{r,t}^{\tau} \right) l_{r,t}^{\tau} F_{r,t}^{\tau} = \mu_t \left[ A \frac{1}{\alpha} \left( 1 - \alpha \right) \frac{1}{(1 + \tau_{X,t})^\frac{1}{2}} \right] N_{n,t} \]

8. First-order condition with respect to \( \theta_t^* \)

\[ \psi_t = h \left( \theta_t^* \right) \sum_{\tau=0}^{L-1} \beta^{\tau} \mu_{t+\tau} \left( c_{r,t+\tau}^r - c_{n,t+\tau}^r \right) + \sum_{\tau=0}^{L-1} \beta^{\tau} \mu_{t+\tau} \left( E_{n} e_{r} l_{n,t+\tau}^{\tau} - E_{r,t} e_{r} l_{r,t+\tau}^{\tau} \right) \]
9. Need to add intensive IC for $\tau = 1, \ldots, T_w$ in $t = 1$ (i.e. assume that $\eta_{n,1-\tau} > 0$)

$$
\sum_{s=0}^{L-1-\tau} \beta^s \log \left( \frac{\tau^{s+1}}{n_{1+s}} \right) - \sum_{s=0}^{L_w-1-\tau} \beta^s \nu \left( \frac{I_{n,1+s}}{r_{r,1+s}} \right) = \sum_{s=0}^{L-1-\tau} \beta^s \log \left( \frac{\tau^{s+1}}{r_{r,1+s}} \right) - \sum_{s=0}^{L_w-1-\tau} \beta^s \nu \left( \frac{F_{r,1+s}}{n_{1+s}} \right),
$$

This can be written as

$$
\sum_{s=0}^{L-1-\tau} \beta^s \log \left( \frac{\tau^{s+1}}{n_{1+s}} \right) = \sum_{s=0}^{L_w-1-\tau} \beta^s \left\{ \nu \left( \frac{I_{n,1+s}}{r_{r,1+s}} \right) - \nu \left( \frac{F_{r,1+s}}{n_{1+s}} \right) \right\}
$$

10. This optimization requires $\eta_{n,t} \geq 0$ for $t \geq 1$, so we need to add the extra-conditions (here we are only writing these equations for $t \geq 1$ as those are the ones for which the extensive margin IC may mean that the intensive IC does not bind)

$$
\sum_{\tau=0}^{L-1} \beta^\tau \log \left( \frac{\tau^{t+1}}{n_{t+1}} \right) - \sum_{\tau=0}^{L_w-1} \beta^\tau \nu \left( \frac{I_{n,t+1}}{r_{r,t+1}} \right) \geq \sum_{\tau=0}^{L-1} \beta^\tau \log \left( \frac{\tau^{t+1}}{r_{r,t+1}} \right) - \sum_{\tau=0}^{L_w-1} \beta^\tau \nu \left( \frac{F_{r,1+t}}{n_{1+t}} \right)
$$

$$
\eta_{n,t} \geq 0
$$

$$
\eta_{n,t} \left[ \sum_{\tau=0}^{L-1} \beta^\tau \log \left( \frac{\tau^{t+1}}{n_{t+1}} \right) - \sum_{\tau=0}^{L_w-1} \beta^\tau \nu \left( \frac{I_{n,t+1}}{r_{r,t+1}} \right) \right] - \sum_{\tau=0}^{L-1} \beta^\tau \log \left( \frac{\tau^{t+1}}{r_{r,t+1}} \right) + \sum_{\tau=0}^{L_w-1} \beta^\tau \nu \left( \frac{F_{r,1+t}}{n_{1+t}} \right) = 0
$$

11. Intensive IC

$$
\theta^*_t = \left\{ \sum_{\tau=0}^{L-1} \beta^\tau \log \left( \frac{\tau^{t+1}}{n_{t+1}} \right) - \sum_{\tau=0}^{L_w-1} \beta^\tau \nu \left( \frac{I_{n,t+1}}{r_{r,t+1}} \right) \right\} - \left\{ \sum_{\tau=0}^{L-1} \beta^\tau \log \left( \frac{\tau^{t+1}}{r_{r,t+1}} \right) - \sum_{\tau=0}^{L_w-1} \beta^\tau \nu \left( \frac{F_{r,1+t}}{n_{1+t}} \right) \right\}
$$

$$
\pi_{n,t} = H(\theta^*_t)
$$

12. Resource constraint

$$
\sum_{i=r,t} \sum_{\tau=0}^{L-1} \pi_{i,t-\tau} c_{i,t} + G_t = \frac{\alpha A^\frac{1}{\alpha}}{1+\alpha} \frac{1}{N_{n,t} + \phi^\frac{1}{\alpha} N_{r,t}}
$$

We start by solving these equations to obtain the steady state, as described in appendix A.2.5. For our calibration, the intensive-margin constraint is not binding in the steady state.

Next, we use a root finding algorithm to solve the transition to this steady state. We assume that convergence to steady state occurs after $T = 50$ periods. To simplify
the computational process, we proceed in steps. We first look for a solution that disregards all intensive margin incentive constraints, i.e., such that $\eta_{n,t} = 0$ for all $t = 2 - L, 3 - L, \ldots$. We check that, in this solution, the intensive-margin constraints of the old generations at time 1 are violated. We then use this solution as an initial guess for a computational algorithm which includes these constraints for every old generation in period 1, i.e., $\eta_{n,t} > 0$ for $t = 1 - L, \ldots, 0$. Next, we check sequentially the intensive-margin constraints are violated for the generations at time $t \geq 1$ and add these to the problem if they are. In our calibration, these constraints do not bind.
